- Getting access to wider and existing markets (globalization);
- Improving service level;
- Assessing present and future market prospects for products and services; and
- To keep up-to-date with technological advancements (Box 2).

Quality Management and Standards in Global Food Supply Chains

The previous section considered logistics processes in global food supply chains. Quality is a key attribute of food products in production as well as in logistics and distribution processes.

Quality management systems enable companies to assure quality and safety of their products and to serve various market segments with the requested quality preferences. Quality management systems encompass elements such as product design, process management, supplier quality management, customer involvement, information exchange, strategic planning, training, and employee involvement. Although most quality management systems include procedures for purchasing, sales and distribution processes, the focus so far is on quality management within firms or from a single firm's perspective.

Gradually, however, attention for intercompany management relationships and chain management has increased in the last decades. Referring to the previous section, a quality management system involving horizontal and vertical dimensions of a chain can provide the means to deal with the complexities related to specific quality characteristics of food products. In this regard, it has been noted that actors in global food supply chains increasingly link their firm level quality management systems. The driving force is the awareness that each actor in a chain can enhance its performance and product quality through aligning its goals and activities with other actors, thus optimizing the results of the whole chain.

In the past decades, many firms have adopted private quality standards to which suppliers have to comply. For example, large retailers have developed initiatives to commit their suppliers globally to strict food safety and environmental regulations and to a high standard with regard to labor conditions. These quality and safety standards require extensive documentation of products and production processes combined with third-party certification and auditing, and strict gathering, storing, processing, and transferring of quality-related information between firms in the chain (Trienekens and Zuurbier, 2008).

In this section, first the typical aspects of quality management in food supply chains are considered, using the pork supply chain as an illustrative example. In Section Tracking and Tracing, public and private standards in global food supply chains will be discussed.

Box 2 Case example: Nike Inc. (Harps, 2004)

Nike is an example of a company, which has possession over the commercial as well as the logistic orchestration. Nike designs sport accessories for all kind of sports and ships products to 143 global destinations. Nike's logistics operations are complex, involving three product lines – footwear, apparel, and equipment – and four regions, managing orders through the company's logistics service provider network. Setting up the network of providers is a collaborative process between the regions and Nike's corporate logistics group. Nike works with two global ocean consolidators, five ocean carriers, four airfreight forwarders, and one courier. The two consolidators (APL Logistics and Maersk Logistics) are responsible for physically handling the cargo from the factory, receiving the freight, loading the containers, communicating to destinations in planning shipment deliveries, collecting documents from the factory, and forwarding them to the destination regions. Nike has chosen to manage its logistics providers in-house rather than outsourcing management to a lead (or fourth-party) logistics provider. The main reason to do so is the complicated supply chain network process, the in-house expertise on supply chain management and the need to stay in constant contact with their customers regarding need dates and freight movement.

Quality Control in Supply Chains – Example of the Pork Chain (Parts of this Section are Based on Trienekens and Wognum (2013))

A food supply chain delivers products to consumers who are at the downstream end of the supply chain. These consumers have differentiated demands with respect to the attributes of the products they consume. In general, intrinsic and extrinsic product attributes are distinguished. Intrinsic attributes can be measured on the product itself and are typical search and experience attributes. Classes of intrinsic characteristics are sensory characteristics such as tenderness of meat or color of fruits, health characteristics such as safety of the product and convenience characteristics such as type of packaging. Extrinsic product characteristics are linked to the production process and, in general, cannot be measured (by consumers) on the product itself. Typical classes of extrinsic attributes of food products relate to animal welfare in various stages of an animal food chain, ecological aspects like waste management, and origin and authenticity of the products.

In Table 3 the example of the pork supply chain is given.

As the aim of food supply chains is to support the end-customer/consumers with superior value, an interesting

Table 3 Intrinsic and extrinsic pork product attributes and indicators

Intrinsic		*Extrinsic*	
Sensory	Tenderness	Animal welfare	Farm production system
	Color		Transportation
	Marbling		Slaughter
Health	Safety (zoonosis)	Ecological food print	Farm manure and waste management
	Food additives		Transportation
	Antibiotics		Slaughter products (high and low value)
	Residues		
Convenience	Packaging	Origin and authenticity	Production location
	Shelf-life		Community impact
	Preparation characteristics		Farm production system
			Processing system

Table 4 Product and production attributes of interest at different pork chain links

Actor	*Attributes valued*
Feed producer	Value added feed mixtures and conversion rate
Breeder	Growth rate, feed conversion, muscle structure, and carcass characteristics
Farmer (farrowing and fattening)	Growth rate, feed conversion, slaughter weight, meat percentage, and muscle structure
Slaughterhouse	Water holding capacity (WHC), intramuscular fat, pH, and tenderness
Processing	WHC and intramuscular fat
Retail	Color, shelf-life, freshness, tenderness, juiciness, and marbling,
Consumer	Taste, tenderness, color, juiciness, marbling, and convenience

question from a food SCM perspective is, whether all stages in the food supply chain are directed at the achievement of the product attributes that are requested by the consumers the supply chain aims at.

In the pork example chain considered, a feed producer is mainly interested in selling feed mixtures with high added value. A breeder will focus more on pig genetics for achieving high growth rate and optimal feed conversion. A farrowing farmer is interested in sow performance and mother behavior. A finishing farmer is also interested in pig characteristics like growth rate, feed conversion, and specific characteristics like meat percentage and muscle structure, because these are the characteristics that he is paid for by the slaughterhouse. However, although the payment system of slaughterhouses is based on these carcass characteristics, the payment of further downstream stages in the supply chain is largely based on process qualifications like weight, size, fat layer, and meat quality characteristics such as juiciness, marbling, and Ph value. Alternatively, for retailers attributes like color and shelf-life are of interest, whereas for consumers these and other attributes like taste and tenderness are of importance. Table 4 shows some of the major attributes as valued by various pork chain partners.

Chain actors can also influence quality attributes of the products they produce in various ways. For example, in the pork meat chain the choice of genotype at the farmer stage will impact on the final meat quality achieved (e.g., Duroc delivers more tender meat and Large White less); at the transportation and slaughterhouse stages limitation of stress at the animal (e.g., by adequate resting time after transportation and CO_2 stunning before slaughter) will impact the final meat quality, as accelerated chilling after slaughter may have. Further, specific diets may influence meat quality, where additives like vitamin E and magnesium may lead to better color and water holding capacity (WHC), respectively. In general, one could say that tuning of production processes throughout the chain to end-customer demands may lead to more differentiated food products that better match with differentiated markets.

A major reason that attributes as valued in the various stages of the supply chain are not aligned is that processes from farm until the slaughterhouse are not directed at end markets, mainly because the payment system of slaughterhouses to farmers does not well relate to final market value. When, for example, the meat percentage is high, fat content will be lower. This means again that tenderness and juiciness (WHC) of the best valued carcasses is lower. The situation is somewhat different for supply chains directed at more differentiated and high-demanding consumer markets. In this type of supply chains, there is a tendency to align processes in the first stages of the chain more with consumer demands. In particular in niche chains like Iberian pigs, Mallorca Black, or Parma pork production in Europe a lot of attention is given to special feed and special meat-processing techniques to achieve the product that the consumer values. Such supply chains can be characterized by a clear vision on the markets they want to serve and the chain-wide approach that is necessary to best serve those markets.

In the last decade, however, globalization of meat distribution networks and large concentration through mergers and acquisition of slaughterhouses and meat processors brought about changes in the organization of the mainstream meat supply chains as well. The large players in these supply chains

are better able to meet differentiated market demand, as they increasingly cover diverse production systems at their input side (e.g., use of different genotypes, free range, etc.) that deliver meat with differentiated quality attributes and at the same time are able to reach more diverse markets globally. For example, fat pork bellies are highly valued in some Asian markets and much less in Western markets.

In the following section, translation of extrinsic quality attributes throughout the pork chain is dealt with. Table 4 mentions three classes of extrinsic attributes of pork products, namely animal welfare, ecological foot print, and origin and authenticity.

Animal welfare

Different stages in the pork supply chain can pay attention to animal welfare. Different levels of animal welfare have been defined which specify, for example, living space for pigs on the farm, feeding regimes through feeding systems where animals can choose themselves when to go for feed or innovative feeding systems that can recognize which pigs already received (sufficient) feed, housing for the pigs, like possibilities to stay outdoor, straw beds instead of slats, and group housing. During transportation small nonmixed groups may have a positive effect on animal welfare. At the slaughter stage, resting time before slaughter, nonuse of electric prods, and ways of stunning (electrical or CO_2) have an impact on animal welfare.

Ecological footprint

Current research indicates that pork supply chains negatively impact the environment. For example, global warming potential of pork ranges from 2.9 to 5.6 kg CO_2e per kilogram carcass weight, depending on the differences in production systems and management (Nguyen *et al.*, 2012). In pig farming, feed production has the most impact on global warming potential. As the largest part of the production cost of a pig is covered by the feed the animal consumes, conversion rate of feed is of ecological interest to the farmer. Manure surplus is the second major contributor to the ecological load of pig farms (Nguyen *et al.*, 2012). Transport is not a major contributor to the negative impact of pork production on the environment (Hermansen and Kristensen, 2011), at least when restricted to regional transportation. Cooled international transportation does have a larger impact. At the slaughterhouse stage, the main impact is from fossil energy use and waste.

Origin and authenticity

In the European Union, authenticity and origin of food are in many cases related to systems known as protected designation of origin (PDO), protected geographical indication (PGI), and traditional specialty guaranteed (TSG) (European Commission (EC), 2006a,b). PDOs are agrarian products or foodstuffs, which are produced, processed, and prepared (almost) exclusively in a given geographical area. The product's characteristics are also the result of the geographical conditions. To obtain a PGI designation at least one of the stages of production, processing, or preparation must be linked to the specified region (European Commission (EC), 2006b). In contrast to PDOs and PGIs, TSGs do not need any specific connection to a geographical area. They are characterized by special attributes of ingredients or processing stages and they must have a traditional background, which means that they must have existed on the market for at least 25 years.

Box 3 Iberian cured ham

Iberian cured ham has four denominations of origin: Dehesa de Extremadura, Guijuelo, Jamon de Huelva, and Valle de los Pedroches. Most Iberian pigs come from the Southwestern regions of Spain, in the 'dehesa' (meadows and woods). Apart from Iberian, there are two other Spanish PDOs in cured ham, Jamon de Teruel and Trevelez. There are two breed designations: 'Iberico puro' from sow and boar of pure Iberian breed with genealogic documentation, and 'Iberico' from pure Iberian sows. Feeding practices in the finishing period (Iberian pigs grow up to 160 kg) are also grouped into four designations: 'Bellota' (finished on a diet of acorn, grasses, etc. in the 'dehesas'); Recebo (finished on partly the same diet as the 'Bellota' animals but with additional concentrates); and Cebo (mostly fed with feed concentrates and sometimes additional acorn and grasses). Bellota and Recebo live a large part of the year in open areas with abundant acorns or fenced meadows. The fabrication of the hams is according to traditional procedures. (Trienekens *et al.*, 2009)

Box 3 depicts an example of a PDO product. In Iberian cured ham production, besides a focus on origin and authenticity, free range keeping of animals is considered to have a positive impact on animal welfare (see Box 3).

The next section will go into food quality and safety standards that are the basis for many quality management systems throughout (global) food supply chains.

Global Food Quality and Safety Standards

Public regulations

On a global level, in particular, the Food and Agricultural Organization (FAO), the World Health Organization (WHO), both United Nations organizations, and the World Trade Organization (WTO) deal with food safety issues. In 1962, as a result of the Food Standards Program, the Codex Alimentarius was established by the WHO and FAO to act as an umbrella organization for policymaking regarding food on a global level. The aim of the Codex is to protect public health and to support balanced trade relationships in food. For this purpose, standards are developed. Codex Alimentarius food standard issues range from specific raw and processed materials characteristics to food hygiene, pesticides residues, contaminants, and labeling, to analysis and sampling methods. Since the establishment of the WTO in 1995, Codex standards are used in trade disputes. Most countries around the world are members of the Codex, covering 98% of the world population. The Codex Alimentarius has great relevance to the international food trade. With respect to the increasing global market, in particular, the advantages of having universally uniform food standards for the protection of consumers are self-evident. It is not surprising, therefore, that the Agreement on the Application of Sanitary and Phytosanitary Measures (SPS) and the Agreement on Technical Barriers to Trade (TBT) both encourage the international harmonization of food standards.

According to the SPS agreement, WTO members are obliged to apply only those measures for food safety and quality that are based on scientific principles and do not constitute a disguised restriction on international trade. Article 2.2 of the SPS Agreement states: "Members shall ensure that any sanitary and phytosanitary measure is applied only to the extent necessary to protect human, animal or plant life or health, is based on scientific principles and is not maintained without sufficient scientific evidence."

On national and international levels also much legislation on quality and safety of food has been established. For example, the EU has developed a wide range of legislative demands with regard to food safety. The EU Directive 93/43 on the hygiene of foodstuffs states that food business operators shall identify any step in their activities critically to ensure food safety and to ensure that adequate procedures are identified, implemented, maintained, and reviewed on the basis of HACCP. The General Food Law of the EU, implemented in January 2005, states the primary liability of food (and animal feed) companies in the event of unsafe products. This implies the implementation of monitoring systems at company level. With information from these systems it should be possible to determine the source of safety or quality problems, and it must be possible to find out where other items with the same problem are located in the supply chain. With regard to traceability, as of 1 January 2005, companies are obliged to keep registration of raw materials supplies and customer deliveries on a transaction basis.

In the USA the FDA Food Safety Modernization Act (FSMA) of 21 December 2010 aims to ensure that the US food supply is safe by shifting the focus of federal regulators from responding to contamination to preventing it.

FDA has a legislative mandate to require comprehensive, prevention-based controls across the food supply. The legislation transforms FDA's approach to food safety, which requires food facilities to evaluate the hazards in their operations, implement and monitor effective measures to prevent contamination, and have a plan in place to take any corrective actions that are necessary. The legislation provides significant enhancements to FDA's ability to achieve greater oversight of the food products coming into the US from other countries.

Private standards

Baseline for private standards

The three most important generic standards for quality assurance in the food sector are good agricultural practices (GAPs), hazard Analysis of critical control points (HACCPs) and International Organization for Standardization (ISO).

GAP systems include a set of guidelines for agricultural practices aiming at assuring minimum standards for production and storage. Important topics are pest management (optimal use of pesticides), manure handling at animal farms, maintenance of water quality, worker and field sanitation, guidelines for postharvest handling and transportation, among others. In the last decades, increasing attention has been given to managerial aspects like documentation, complaint and recall procedures, labeling, etc. HACCP is a systematic approach to the identification, evaluation, and control of those steps in food manufacturing that are critical to product safety. Currently, HACCP principles are the basis of most food quality and safety assurance systems (Codex Alimentarius, EU and US food legislation). HACCP identifies risks in the production processes that can lead to unsafe products, and designs measurements to reduce these risks to acceptable levels. HACCP aims at prevention of hazards instead of end-of-pipe inspection. It is basically designed for application in all links of the food chain, ranging from growing, harvesting, processing, distribution, and retail to preparing food for consumption (Box 4).

Box 4 HACCP

HACCP involves seven principles:

- Analyze hazards (biological, chemical, or physical);
- Identify critical control points (these are points in a food's production at which the potential hazard can be controlled or eliminated);
- Establish preventive measures with critical limits for each control point;
- Establish procedures to monitor the critical control points;
- Establish corrective actions to be taken when monitoring shows that a critical limit has not been met;
- Establish procedures to verify that the system is working properly; and
- Establish effective recordkeeping to document the HACCP system.

Preconditions for HACCP implementation are: sanitary design principles (e.g., linear product flow), GMP, and safety programs should be present; written specifications for all ingredients, products, and packaging materials should be present; sanitary design principles and maintenance schedules should be present; personal hygiene requirements, documented procedures to assure segregation and proper use of nonfood chemicals should be in place; traceability and recall procedures should be in place, etc.

Although GAP and HACCP pay attention to both technological and management issues, ISO focuses on management. The most used of all ISO standards is the ISO 9000 series for quality. These standards are independent of any specific industry. In the 2000 version (ISO 9001:2000) the objectives are: achievement of customer satisfaction by meeting customer requirements, continuous improvement of the system and prevention of nonconformity. In 2005, the ISO 22 000 standard, specifically aiming at managing safety in the food chain, has been published. It is a specific standard for food processors setting out safety management procedures. The standard applies to organizations ranging from feed producers, primary producers through food manufacturers, transport and storage operators and subcontractors to retail and food service outlets. The standard extends the ISO 9001:2000 quality management system standard, which is widely implemented in all sectors but does not specifically address food safety.

Private food safety and quality standards

Since the 1990s many private food quality and safety standards have been developed.

Standards can be set up to specify quality attributes of a product, including origin and authenticity, and production and processing methods. Increasingly, they include sustainability and ethical specifications relating to environmental impact, animal welfare concerns, and worker conditions.

Table 5 Quality standards in global food supply chains

System	*Based on*	*Origin*	*Aim/set up of the system*
British retail consortium standard (BRC)	HACCP and ISO	British retailers	Requires an operational quality system and an HACCP plan that includes environmental issues, product, process, and staff. Aims at processing/distribution stage of the chain
International Food Standard	HACCP, ISO, and BRC	German, French, and Swiss retailers	Aims to ensure food safety and the quality level of retailer-branded food products. Aims at processing/distribution stage of the chain
Safe Quality Food	HACCP and ISO	Australian retailers	Addresses not only food safety and quality, but also other issues such as animal welfare, environmental impact, ethical production, organic production, and religious preparation requirements. Aims at all stages of the chain
International Standard Organization (ISO 22 000)	HACCP	ISO	Management standard for any organization in the food chain, including feed producers and service providers
Retailer produce good agricultural practices (Global-GAP)	HACCP	European and US retailers	Global-GAP supports the use of HACCP and members are obligated to comply with national and international legislation. Primary producers have to show commitment to issues such as reduction of environmental damage, pesticide use, and efficient use of natural resources, health and safety for employees and traceability efforts

Abbreviations: HACCP, hazard analysis of critical control points; ISO, International Organization for Standardization.

The aim of standards is to:

- Ensure product quality attributes as well as origin and production methods used;
- Improve supplier standards and consistency and avoid product failure;
- Eliminate multiple audit of food suppliers and manufacturers through certification of their processes;
- Reduce transaction costs; and
- Serve as strategic tools for market penetration and competitive advantage of food supply chains.

Table 5 describes examples of globally applied standards. Being largely based on HACCP and ISO hygiene and food safety regulations, these systems are similar in many respects.

Besides the quality assurance standards that focus on quality and safety of food, standards that pay major attention to extrinsic characteristics, like sustainable 'Utz' coffee or Chiquita's 'Rainforest alliance' bananas are now increasingly observed. Moreover, in Europe there is an increasing number of PDO that are labeled as such to create extra value added. Although until recently these specific product and processing attributes were aimed for niche markets in Western countries, some of the extrinsic product attributes, such as animal welfare or sustainability attributes, are now swiftly integrated in basic retail and industry standards as indicated above. However, the design of new niche market-directed standards seems to be an ongoing process. Table 6 depicts typical extrinsic food product characteristics that might, given the developments depicted in the table, increasingly be included in quality assurance standards.

In general, three levels of quality standards can be distinguished. The base level comprises public regulations and standard baseline standards such as HACCP that are legally required in most Western countries. The second level consists of private standards that are widely applied by retailers and industry across the world and that, although not legally required, have become compulsory for food producers to get access to these particular buyers. However, above these private 'compulsory' systems layer, another layer of standards with even more specific demands has evolved. Well-known examples are Tesco's 'Nature's Choice,' which puts a number of environmental demands on top of Global-GAP demands, PDO labels, and fair-trade labels. In this perspective, it is expected that proliferation of standards will continue, only on a different level as was the case so far. Figure 5 depicts this three-layer model for quality system standards.

The Global Character of Food Safety and Quality Standards

In industrialized countries, most companies in the food chain comply with basic standards on food safety and quality. For developing countries and emerging economy producers the situation is more difficult.

Table 7 depicts the major trends, bottlenecks, and opportunities related to food quality and safety in Western Organisation for Economic Cooperation and Development (OECD) economies, emerging economies, and in developing countries.

Table 7 shows that the OECD countries especially focus on consumer-related topics with regard to quality management. Consumers increasingly are aware of safety and quality problems and companies should increasingly focus on consumers for the execution of food quality and safety management, for

Table 6 Extrinsic product attributes that might be included in production standards

Extrinsic attributes	*Consumer and governmental demands*	*Developments*
Process technology	• Animal welfare	• Increasing legislation on animal welfare
	• Nature of production system (e.g., traditional and organic)	• Increasing consumer interest in regional and 'natural' production
	• Feeding regime	• Strict legislation regarding animal feed content
	• Transportation distances	
	Input materials (fertilizers, pesticides, etc.)	Risk-based inspections of products (e.g., products from countries considered high-risk countries are inspected more often)
	Biotechnology	Consumer reluctance in EU (e.g., against gene technology)
Impact on environment, people, and society	Environment	• Attention of leading retailers (e.g., Tesco, UK) for environmental aspects in labeling
	Manure disposal	
	Deforestation	• Attention of global food companies for sustainability issues (e.g., Rain Forest Alliance label at Chiquita bananas)
	Pollution	
	Packaging	
	Food miles	• Strict legislation against manure disposal
	Global warming	
	Working conditions	• (International) legislation against child labor
	Child labor	• Corporate Social responsibility (CSR) policy at many multinational companies
	Contracts	
	Education, housing legal rights	
	Community	CSR policy at many multinational companies
	Educational support	
	Economic development	
	Healthcare	
Supply and demand	Fair trade	Increasing consumer attention for fair-trade products
	Procurement	• Stricter legislation of Western countries against unethical practices
	Favoritism	
	Bribery	• CSR policy at many multinational companies

example, through traceability systems covering the whole chain. Communication about food safety and quality in the chain can be further improved, for example, dissemination of R&D knowledge. Currently, food chains have to comply with many private and public demands on quality and safety, which may result in multiple audits, although harmonization efforts have been successful at the level of the private 'compulsory' systems (see Figure 5). In this regard the Global Food Safety Initiative, initiated by a number of global retailers, has put a lot of effort in harmonization of these systems. However, companies are also involved in developing innovative products, such as organic products, and packaging materials, complying with new standards.

Emerging economies are focusing on developing new markets, both national and international. Several of these countries (Brazil, China, and India) have considerable home markets, but due to the unequal income division, requirements on these markets differ heavily, which results in the development of separate supply chains including different quality requirements for national and international markets. In fact, this group of countries is in the middle of a process of awareness and adoption of quality and safety regulations both for government as for the business. The design of organizational and governmental structures for ensuring food safety and quality has priority. In this regard, food safety policies are greatly influenced by the requirements of international trade. A major challenge is that food control is not adequately done, there are very few activities involving preventive inspection, little attention is paid to education of these standards and the sanction system is weakly developed.

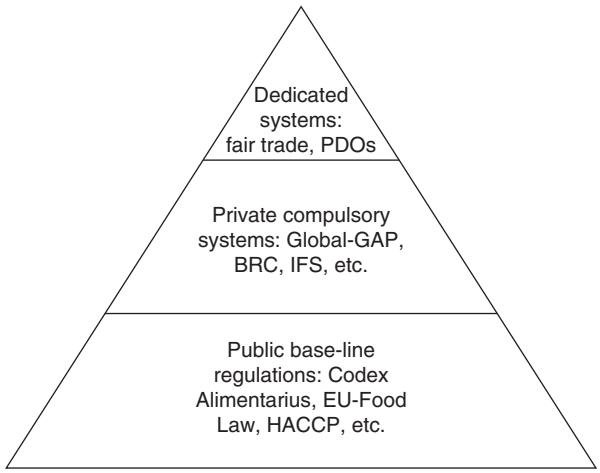

Figure 5 The three-layer model of quality standards. Reproduced from Trienekens, J.H., Zuurbier, P.J.P., 2008. Quality and safety standards in the food industry, developments and challenges. International Journal for Production Economics 113 (1), 107–122.

Developing countries are in a phase of discovering quality and safety of food as important conditions of international food trade and in many cases have to start from scratch or build on Western standards (Box 5).

Table 7 Trends, bottlenecks, and opportunities in international food chain development in different countries and regions

	Trends	*Bottlenecks*	*Opportunities*
Organisation for Economic Cooperation and Development (OECD) economies	• High consumer awareness regarding food safety and quality • Innovative materials/ products • Niche market development	• Limited communication on food safety and quality attributes • Limited knowledge of consumers on food safety and quality • Low dissemination of research and development knowledge on food safety and quality • Many private quality labels and public quality regulations	• Traceability to gain consumer confidence • Knowledge and experience dissemination • Chain-wide monitoring to ensure safety and quality of food • Possibilities for self-regulation for food companies
Emerging economies	• Focus on international markets (beef, soy, orange, coffee, pork, etc.) • Increasing local markets (e.g., Brazil, Russia, and China)	• Uneven income distribution • Lack of coordination (horizontal and vertical) • Lack of infrastructure (cold chain and roads/ports)	• Design of two coordinated subsystems on agrifood: (a) high quality for modern market segments and (b) average (but safe) quality for local market • Standards (PP) harmonization within countries and among countries • Coordination to improve inspections and enforcement
Developing countries	• Development of codes and standards • (Slowly) improving infrastructure/distribution • Producer collaboration	• No laboratories to analyze samples • No investments in transport and storage • Lack of legal framework and enforcement • Lack of market information • Lack of skilled/educated people	• Asia and Middle-East as new markets with less strict quality assurance standards • Improving feed and feeding system • Public/private network development • Cheap labor costs

Box 5 EU-regulation-based quality standard in Uganda and Kenya

The quality standard for fish in Uganda is based on EU directive 91/493/EEC and on Codex Alimentarius. The standard covers the following fields: microbiology levels, pesticide residues, heavy metals, effluents, Good Manufacturing Practices (processing stage), and HACCP (processing stage). For its export of fruit and vegetables, Kenya complies as much as possible to the UK's Food Safety Act of 1990.

Moreover, SPS and TBT often constitute barriers for export from developing countries to industrialized countries and producers at most times lack awareness and adequate information about specific demands of (the variety of) western standards. Important issues often deal about what, which, and how quality regulations and systems should be adapted. Moreover, the building of facilities to improve quality regulations and the building of governmental structures for ensuring quality and safety of products are key points of attention. Investments in (cooled) transportation and storage are necessary to effectively participate in international trade. The governments must encourage financial institutions to avail credit to farmers and play a facilitating role by providing market information, education, and the establishment of standards. Further, there is an opportunity for governments of these countries to work together in order to adopt a common stance and generate consensus with regard to trade negotiations in the WTO.

A big challenge for many developing country producers is the high costs of implementing and maintaining standards. In the last decade, however, initiatives from large industries (such as Unilever and Nestle) for collective certification of farmers have been observed.

Standards as organizational arrangements in global supply chains

Relationships between actors in global food supply chains are often hindered by uncertain supply markets and weak monitoring and enforcement regimes, although high investments are often necessary. Therefore, these relationships have to be safeguarded by the right organizational arrangements (governance mechanisms). In general, a distinction can be made between formal and informal governance mechanisms. Formal governance mechanisms include vertical coordination and (formal) contracts (Williamson, 1985, 1999). Informal governance mechanisms include informal agreements, trust, commitment, and reputation.

Quality and safety assurance standards, in many cases supported by third party certification organizations, are a formal governance mechanism through which coordination and control of quality attributes and safety of food products are assured. These standards are in most cases also included in bilateral (formal) contracts between parties in global food supply chains. However, as even specified arrangements do not

always guarantee compliance to standards and integrity of the information exchanged, informal governance mechanisms such as trust and commitment based on long-term relationships play an important role in compliance with customer demands and safeguarding information exchange in the supply chain. In this respect, trust often replaces more integrated governance mechanisms to safeguard against opportunistic behavior (Gulati, 1998). This article will not go further into governance arrangements in global food supply chains, as its focus is on operations. For further reading, refer to Williamson, 1999; Gulati, 1998; Gereffi *et al.*, 2005; Kaplinsky, 2000; Ruben *et al.*, 2007.

Box 6 StarBucks' Coffee and Farmer Equity practices

The Starbucks' Coffee and Farmer Equity (CAFÉ) Practices Program includes a broad set of social, economic, environmental, and quality guidelines developed by Starbucks in collaboration with Conservation International. The program started in 2001, as a response to pressure placed on Starbucks during the late 1990s by NGOs. The CAFÉ practices standard promotes coffee production practices that protect biodiversity, maintain healthy ecosystems, and support economic and social development in coffee production. To support the quality guidelines, Starbucks offers technical support via farmer support centers. Compliance with the standard is verified by a range of third-party verification organizations.

Transparency in Food Supply Chains

Transparency of information is an essential issue in food supply chains for logistics management and to guarantee food quality and provenance to all users of food and food products. More specifically:

1. Consumers require more and more information about the origin of products and the way the product is produced.
2. A reliable exchange of quality and health data throughout the chain provides actors with an instrument to better plan their production and sales processes and better match the right quality to the right market.
3. Availability of operational quality and safety data across the chain supports adequate risk management.
4. The increasing complexity of logistics flows caused by product differentiation, market segmentation, and internationalization, demands insight into production and stock data throughout the food chain, so that companies can make better forecasts and more effectively plan logistics and distribution processes.
5. On the basis of experience gained during the recent crises in the global food sector, traceability has shown to be a key capability for companies to find the origin of problems and recall hazardous products quickly.

Transparency Demands

As described in Section Global Supply Chain Management and Logistics, besides sensory, health and convenience (intrinsic) product attributes, consumers increasingly put demands on process (extrinsic) attributes. These extrinsic demands pose a number of information exchange challenges to actors in the food supply chain as people and organizations must be informed with integrity about these attributes.

For the government the main incentives to support food supply chain transparency include protection of public health through timely withdrawal of unsafe products, to prevent fraud regarding food product authenticity, and to control livestock diseases (such as classical swine fever).

The industry motivation regarding transparency is fourfold: first, companies need to comply with differentiating demands from consumers as well as legislative demands as described in the previous section. Second, when incidents occur companies are required and want to be able to quickly recall products from markets or links downstream the supply chain to limit the impact of the incident and minimize costs. Third, by improving information exchange through integrated information systems, optimization of business processes will be much easier as product and process attributes can be coupled with process performance. Fourth, an important way for food companies to add value is by paying attention to and labeling products according to distinguishing intrinsic and extrinsic food product attributes, such as those listed in the previous section. In the last decade, many companies in the food sector have been stimulated to implement corporate social responsibility strategies in which special attention is paid to ethical aspects of production and procurement. For example, supermarkets increasingly sell ethical responsible products, such as chocolate, with cacao produced according to fair-trade principles (Box 6).

By implementing transparent and integrated information systems supporting transparency aims, organizations can improve their image as they can propagate that products satisfy specific quality (intrinsic and extrinsic) demands. As referred to earlier, other motivations are logistical optimization, quality assurance, and process optimization.

Tracking and Tracing

The required ability to trace products back to their origin and production methods and to track the ongoing location of products has forced companies worldwide to implement coordinated information systems along the food supply chain.

The basic idea of tracking and tracing is the possibility to determine where a certain item is located and to trace the history of that item (**Figure 6**, van der Vorst, 2006):

- Tracking of items: the determination of the ongoing location of items during their way through the supply chain.
- Tracing aims at defining the composition of an item and the treatments that item has received during the various stages of the product life cycle. Chain upstream (backward) tracing aims at determining the history of items and is used to determine the source of a problem of a defective item. Chain downstream (forward) tracing aims at the determination of the location of items that were produced using, for example, a contaminated batch of raw materials.

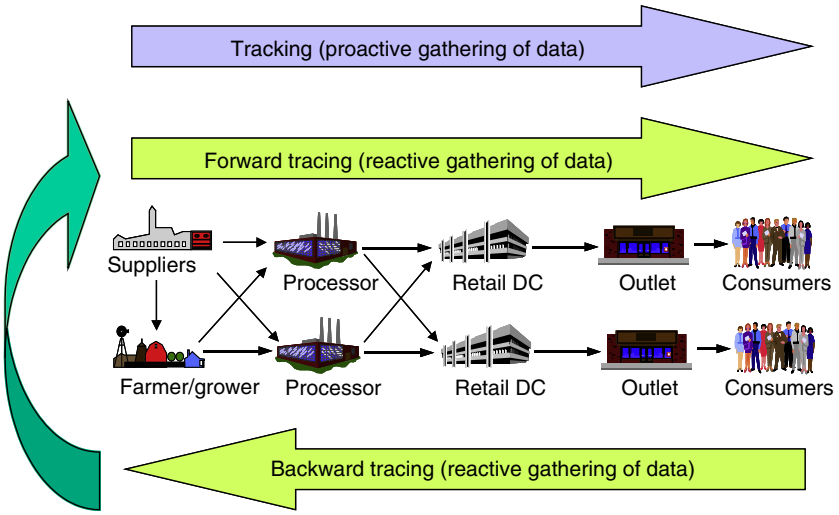

Figure 6 Tracking and tracing. Reproduced from van der Vorst, J.G.A.J., Beulens, A.J.M., van Beek, P., 2005. Innovations in logistics and ICT in food supply chain networks. In: Jongen, W.M.F., Meulenberg, M.T.G. (Eds.), Innovation in Agri-Food Systems. Wageningen: Wageningen Academic Publishers, pp. 245–292. (Chapter 10, ISBN 9076998655).

Tracking and tracing in food supply chains is a challenging issue. There are many sector-specific characteristics that complicate tracking and tracing, such as the following:

- The sector is characterized by high flow complexities. Food supply chains often combine continuous product flows (bulk, traced in volumes/weight) and discrete product flows (countable, traced in units). For tracking and tracing these mixed flows lots of bulk products downstream have to be linked with packaged products upstream.
- The lots of food product have to be clearly separated in order to prevent contamination. In particular for the continuous flows in food supply chains this is not easy to implement.
- Many food supply chains consist of alternating diverging and converging processes and byproducts. There are many composite products consisting of many components, including ingredients and packaging. All these components have to be tracked and traced. Food supply chains result also in a lot of waste and byproducts, which have to be tracked and traced as well.
- The product flows in different food supply chains are highly interdependent, for example, byproducts of one end product are input of other food products.
- Food products are natural products with a high perishability (in particular fresh food). There are also high demands from consumers and society, including food safety legislation, and quality standards. As a consequence traceability information must include additional information such as best-before-dates, country of origin of the ingredients, and certificates for quality, phytosanitary/veterinary, and ecological inspections.
- Food supply chains have a complex network structure where small and medium enterprises (farms and parts of the processing industry) trade with huge multinationals in the input and retail sector. Many food supply chains are also very international, among others to ensure a year-round-supply of seasonable products. As a consequence, supply has to be collected from many small producers all over the world that all have to be tracked and traced properly.

To enable tracking and tracing, detailed registration of process, resource, and product characteristics, such as origin and history of products, quality variation, etc., is essential for the food industry. Product information concerns the composition and sensory aspects of the products, as well as residue information (e.g., pesticides and hormones). Process information to be exchanged includes the origin of the product (and its components in the case of a composite product); the history of the product (where the products has been on its trajectory through the food supply chain and who has dealt with it), storage time and quality decay, quality variation within and between different product lots and resources used and waste.

A large actuality gap between the occurrence of events and recording of data is often a problem when systems have to be used more or less in real time, like in the case of product recalls. In many cases, it has been a (sometimes too) big challenge to timely and adequately link a food incident to data recorded earlier in time.

Virtualization of Food Supply Chains

Traceability systems focus on the information to track the location of certain items and to trace the history of that item. Building on these systems and utilizing new internet and sensor technologies, food supply chains can increasingly be virtualized, which implies that not only the location of items ('whereabouts') can be tracked and traced, but also the dynamic properties including quality conditions.

Virtual supply chains combine the perspectives of virtual organizations and virtual things (Verdouw *et al.*, 2012). Virtual organizations are dynamic organizational structures that temporally bring together resources of different organizations to better respond to business opportunities (Davidsow and

Malone, 1992; Goldman *et al.*, 1995; Venkatraman and Henderson, 1998). The virtual things perspective is related to the Internet of Things (IoT), which provides a vision of a world where physical objects are connected real-time to the internet. Virtual supply chains combine these two perspectives and can be defined as dynamic organizational structures that temporally bring together resources of different organizations based on the virtualization of the physical logistic objects such as containers, shipments, products, trucks, and vessels. The virtualization of physical objects allows for the decoupling of the physical and information aspects of logistics operations (Clarke, 1998). The actors responsible for planning, orchestration, and coordination are not necessarily also the ones handling and observing these physical objects and they can be at totally different locations. As a consequence, virtualization enables the decentralization or decoupling of physical flows from (centralized) planning, orchestration, and coordination taking place in other locations and by other partners.

Information systems can enable these virtual logistic networks with flexible chain-encompassing tracking and tracing systems and decision support based on that information. These systems effectively virtualize the logistics flows from farm to fork, support a timely and error-free exchange of logistics information, and provide functionality for intelligent analysis and reporting of exchanged data to enable early warning and advanced forecasting. Three critical features of these systems are distinguished (Verdouw *et al.*, 2013): real-time virtualization, logistics connectivity. and logistics intelligence (**Figure 7**).

Real-time virtualization

The interaction between real/physical and digital/virtual objects as apparent in the (IoT) is an essential concept of virtual logistic networks. In the IoT, physical entities have digital counterparts and virtual representations; things become context aware and they can sense, communicate, interact, exchange data, information, and knowledge (Guillemin and Friess, 2009). In other words, each physical object is accompanied by a rich, globally accessible virtual object that contains both current and historical information on that object's physical properties, origin, ownership, and sensory context (Welbourne *et al.*, 2009). Geographically dispersed physical objects have to be tied to and continuously update a virtual representation of the object, i.e., (lots of) products and logistic resources such as containers. The virtual objects must 'adequately' represent the identity, place, and (dynamic) properties of the (physical) objects of interest; they must be 'reliable' for different purposes of usage; they must be timely available and the security and privacy must be unquestionable.

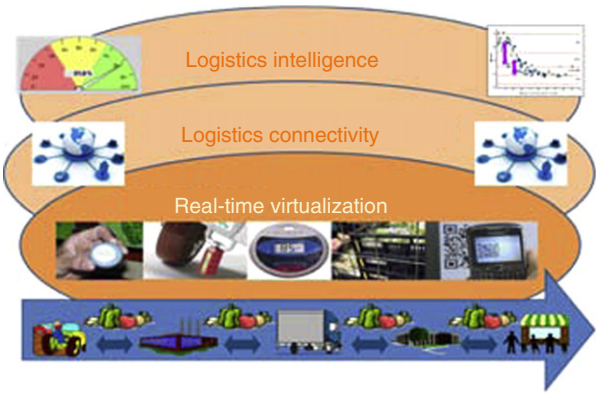

Figure 7 Virtualization of food supply chains.

A complicating factor in the food and agribusiness is that the properties of agrifood products are highly dynamic because they are living products. Furthermore, virtual objects must provide multiple views for different users, having distinct purposes of usage. Visualization plays an important role to create views that are experienced by human users as reality. Promising enabling technologies include advanced visioning technologies (including high-speed/low-cost solutions, 3D, and internal features such as ripeness), the mixture of real and virtual objects in augmented reality (including mobile applications), and in particular the combination of both the technologies.

Logistics connectivity

The internet acts as a storage and communication infrastructure that holds a virtual representation of things linking relevant information with the object (Uckelmann *et al.*, 2011). As such, virtual objects serve as central hubs of object information that combine and continuously update data from a wide range of sources. Logistics connectivity is of vital importance to enable timely, reliable, secure, and flexible data communication. This in particular requires (1) solid infrastructures to communicate information of objects while safeguarding property, access and usage rights and (2) standards for a seamless identification and exchange of product/logistics data. An important underlying challenge in virtual networks is to find solutions to support rapid configuration and the combination of federated and centralized solutions.

Logistics intelligence

The usage of dynamic virtualization data for intelligent decision support is an important future challenge. The shared information needs to be appropriate for planning, coordination, orchestration, and control of the logistics network. Therefore, information systems must support the intelligent analysis and reporting of exchanged data. These functionalities enable early warning in case of disruptions or unexpected deviations (e.g., in lead time, temperature, etc.) and advanced forecasting about consequences of detected changes by the time the product reaches destination.

Information Technologies Enabling Transparency of Food Supply Chains

The information intensiveness is very high in food supply chains. A lot of information must be continuously captured, edited, and communicated throughout the food supply chain to ensure the transparency needed for the tracking and tracing of food products from farm to forks as well as for the virtualization of planning and control. Automating these information-processing activities in information systems is of vital importance to make the resulting complex, frequent and interenterprise information flows manageable.

Information systems make it possible to share supply chain information in an efficient, timely, secure, and reliable way. The main enabling technologies are discussed below.

Automatic identification and data capture

Automatic identification and data capture (AIDC) is concerned with technologies that automatically identify objects, collect data about them and enter that data directly into computer systems. In the food sector, important AIDC technologies are barcoding, radio frequency identification (RFID), and in the future biometrics as well (e.g., deoxyribonucleic acid (DNA) technology). Pork and veal supply chains, for example, use RFID tags in ear labels to identify the animal throughout the supply chain until the processing stage. In recent years, the application of RFID in animal supply chains was extended to automatic identification (through readers) at feeding stations, enabling the adaptation of feeding and medicine use (mixed with the feed) to the individual animal, automatic weighing and selection of animals, temperature measurement to identify sickness of the animal, etc. RFID is also increasingly used in vegetables and fruit and in processing companies to identify lots of products. This enables adequate management of production and distribution processes and traceability and recall management. The use of DNA technology will be increasingly viewed as a promising solution to check provenance of food products.

Quality monitoring technologies

The monitoring of quality parameters is an essential issue in food supply chains that deal with fresh products. It is an important basis for quality-controlled logistics, that is, advanced logistics decision making taking real-time information on product quality behavior into account (van der Vorst *et al.*, 2011). Important enabling technologies are fixed sensors, advanced barcodes, data loggers, time–temperature Indicators, RFID-enabled sensors, and wireless sensor networks.

Enterprise information systems

Like in other industries, data captured in enterprise information systems are used for the planning and evaluation of production. These information systems support the processing of information at different levels ranging from (technical) operational to strategic. Here it is worth referring to examples such as warehouse management systems, specifically designed for the food industry for quality-controlled storage and distribution processes; laboratory information management systems, for quality and safety control of certain product lots or (groups of) animals; and the more generic enterprise resource planning (ERP) systems for integrated planning purposes. The applicability of ERP in the food sector is often considered to be limited, in particular in fresh food supply chains. Many ERP systems lack food-specific functionalities and the rigid planning and scheduling systems of traditional ERP systems may cause problems in the highly dynamic food sector. However, this situation is changing. The ERP industry has acknowledged the lack of flexibility and in the previous decade it has worked hard to transform ERP into web-based systems that are componentized based on service-oriented architecture. Furthermore, many sector-specific ERP solutions have emerged, also in the food sector.

Information integration

The previous technologies support the basic registration of data that are needed for tracking and tracing and supply chain virtualization. These data have to be shared within the supply chain via integrated information systems in order to create transparency. There can be defined four levels of integration (Wolfert *et al.*, 2010):

- Physical integration: technical infrastructure to enable communication between hardware components.
- Data integration: alignment of data definitions in order to be able to share data.
- Application integration: alignment of software systems so that one system online can use data generated by another one.
- Process integration: alignment of tasks by coordination mechanisms.

A rapid, error-free and efficient information transfer is only possible when information systems in the chain 'speak the same language.' This can be realized by basing information standards on business processes. These standards are fixed agreements on the size, contents, and meaning of the information (messages and coding) that is exchanged and the way in which these have to be communicated technically (via internet of labels). The most important information standards for the different integration level are (Wolfert *et al.*, 2010) the following:

- Standardization of the physical communication infrastructure makes it technically possible to connect products, hardware, machines, devices, and their operating systems. In general, standardization at this level is very mature, although new technologies are emerging, requiring new standards (e.g., RFID).
- Standardization for data exchange focuses on the format of messages and data definitions. The eXtended Markup Language (XML) has succeeded Electronic Data Interchange technology as the leading basis for data exchange standards.
- Application integration is mainly supported by standards for web services, that is, autonomous, reusable software components that are based on XML message technology that can be described, published, and invoked over the internet.
- Standards and reference process models that support design of integrated intra- and interenterprise business processes (Verdouw, 2010).

Many of the standards needed in food supply chains are not sector specific, in particular the technical standards, identification standards, and generic message standards. GS1, the international association that develops and implements standards for use in logistical systems (unique coding of product entities, transportation entities, etc.), is one common and standardized infrastructure to facilitate the efficient and effective exchange of data in the supply chain. Food-specific standards are mainly related to semantics for data exchange and process integration.

Supply Chain Information Systems

Supply chain information systems are software systems that support the rapid, error-free, efficient, and safe information exchange between supply chain participants, including systems

for tracking and tracing and supply chain planning. In collaborative supply chain environments, where there is close collaboration between horizontally and vertically linked companies in the food chain a joint infrastructure consisting of networks, coding standards, and integrated or coupled databases is established. Large companies, for instance slaughterhouses in meat supply chains, design their own systems to communicate with suppliers and for analysis purposes. Furthermore, increasingly small producers start collaborating through integrated information exchange, supported by third party service (software) providers. Integrated or coordinated databases at various network partners serve as the backbone of these integrated supply chain systems. The goal of these systems is the exchange of (quality performance and safety) data to enable transparency in the chain and to optimize processes throughout the chain.

However, in food supply chains that lack a dominating company, the adoption of centralized systems advances only with difficulty. Important limiting factors are a lack of intraenterprise interoperability and organizational factors such as unclear business models and a lack of trust in the privacy of data. Furthermore, the technology is complex. In particular, SMEs miss the competences and mass needed for implementation. As a consequence, the emphasis in this theme is shifting toward distributed software applications based on web services that support a rapid, reliable, secure, and flexible data communication.

In this section, it has been shown how information exchange in food supply chains is supported by information systems and information technology and that increasingly flexible systems are needed to be able to meet the broad range of information required by various chain actors and consumers (groups) and governments worldwide. However, although information systems and technology can enable and support information exchange and transparency in food chains, they can never guarantee the integrity of information and transparency that is wished for. Therefore, the authors state that trusted information exchange and transparency always imply a good match with supporting organizational arrangements (e.g., contracts and trust) and compliance with quality and safety standards.

Glossary

Crop-revenue insurance Deficiency payments have been largely replaced by crop-revenue insurance, which guarantees farmers fixed total revenues for their crops (based on acreage and average historical yield) regardless of fluctuations in price or yield.

Deficiency payment In US agricultural policy, the expected deficiency payment for a particular crop, c, is $E(d_{ct}) = \left[P_{ct}^{T} - \text{Max}\left(P_{ct}^{S}, E(P_{ct})\right)\right](1-\omega_{ct})L_{ct}Y_{ct}$, where P_{ct}^{T} is the target price; P_{ct}^{S}, the support price; $E(P_{ct})$, the expected average price received by farmers; ω_{ct} the percentage of land base required to be idled; L_{ct} the land base in period t; and Y_{ct}, the program yield per unit of the land base.

Nominal rate of assistance (NRA) The NRA measures market distortions imposed by governments that create a gap between the current domestic price of a product and the price that would exist under free markets. Under the 'small-country' assumption, this rate is computed as the percentage by which government policies have raised gross returns to farmers above what they would have been had the government not intervened (or the percentage by which government policies have lowered gross returns, if NRA <0). It, therefore, includes the effect of not only output-price-distorting policy instruments but also measures that alter the cost of farm inputs.

Relative rate of assistance (RRA) The RRA is defined in percentage terms as

$$\text{RRA} = 100 \times [(100 + \text{NRAag}^{t})/(100 + \text{NRAnon} - \text{ag}^{t}) - 1]$$

where NRAag^{t} and NRAnon-ag^{t} are the percentage NRAs for the tradable parts of the agricultural and nonagricultural sectors, respectively. If both of these sectors are equally assisted, the RRA is zero. This measure is useful in providing an internationally comparable indication of the extent to which a country's sectoral policy regime has an anti- (or pro-) agricultural bias. The RRA recognizes that farmers are affected not just by prices of their own products and inputs but also by the incentives faced by nonagricultural producers bidding for the same mobile resources.

Trade-reduction index (TRI) TRI measures the extent to which import protection or export taxation reduces the volume of trade. The TRI is defined as the percentage uniform trade tax which, if applied equally to all agricultural tradables, would generate the same reduction in trade volume as the actual intrasectoral structure of distortions to domestic prices of such tradable goods.

Welfare-reduction index (WRI) The percentage uniform trade tax which, if applied equally to all agricultural tradables, would generate the same reduction in national economic welfare as the actual intrasectoral structure of distortions to domestic prices of these tradable goods. The WRI recognizes that the welfare cost of a price distortion imposed by a government is related to the square of the price wedge and thus is positive, regardless of whether the government's policy favors or hurts producers in a particular sector.

Introduction

Agricultural policy in the United States is a complex and evolving web of governmental interventions in output markets, input markets, trade, public-good investments, renewable and exhaustible natural resources, regulation of externalities, education, and the marketing and distribution of food products. For the US federal government, these interventions have resulted in enormous budgetary costs, huge surpluses of farm products, major disputes with other countries, distorted international markets, and special benefits to interest groups that are often highly concentrated. These same programs, however, have contributed to an agricultural sector whose productivity over much of the last century has been spectacular.

Early US Agricultural Policies

In the second half of the nineteenth century, the US federal government began to design and implement programs to increase growth in the agricultural sector. From 1850 to the early 1900s, important institutions aimed at lowering transaction costs in the private sector began to emerge. For example, the Morrill Act of 1862 offered federal land grants to states so they could establish free, public institutions of higher education. Even at the outset, agricultural science research was a crucial component of these institutions. The US Department of Agriculture (USDA) was also created in 1862. It focused initially on collecting and disseminating research and designing regulations. In 1887, the Hatch Act created the Agricultural Experiment Station system by providing annual agricultural research grants to each state. In 1914, the Smith-Lever Act set up the nationwide Cooperative Extension Service, whose purpose was to provide new agricultural technologies and knowledge directly to farmers through a network of agents in each county of each state. The Cooperative Extension Service proved effective, partly because it served as the conduit for farmers to communicate back to the USDA and to the land-grant universities information about obstacles that needed to be researched.

These early federal policies can be generally characterized as long-run institutional developments: the government was supplying public goods whose associated benefits and costs

 doi:10.1016/B978-0-444-52512-3.00119-4

were widely dispersed. In the next phase, beginning in the 1930s, the US agricultural policies focused on controlling supplies of commodities in order to increase market prices and net farm income. The agricultural industry was highly competitive, and competition gave individual producers incentive to adopt new technologies that would augment productivity and market supply. However, the inelastic aggregate demand for agricultural commodities meant that a large increase in supply would result in unacceptable price declines. Over time, this combination of low-demand elasticity and a high rate of innovation exerted downward pressure on agricultural and food prices. Not surprisingly, income and wealth in the agricultural sector often declined. Moreover, as agriculture is based on natural resources, it is vulnerable to productivity changes due to climate fluctuation, pest infestation, and other environmental factors. Thus, in addition to declining prices, farmers are often exposed to price instability.

In sum, the declining rate of profitability and return on agricultural assets over time generated economic incentives to reallocate resources away from agriculture. However, agricultural capital (both physical and human) are specialized, so that there are barriers to reallocating them to other sectors. As a result, owners of agricultural assets and skills have been left with little flexibility to respond to worsening terms of trade. This dynamic led historically to what was termed the 'agricultural problem' of decreasing prices, low income, and rural poverty (Schultz, 1964; Cochrane, 1958).

The tendency for pockets of rural poverty to persist in US agricultural regions led the government to develop policies aimed at raising farm income and supporting the value of agricultural assets. Thus, price and income support have become major features of agricultural policy since the 1930s. The instability of agricultural supply, which has affected both the well-being of farmers and the availability of food to consumers, also spurred the establishment of policies designed to stabilize supply of agricultural commodities. The vulnerability of agricultural crops to climatic and environmental conditions also motivated the introduction of governmental programs that extended beyond price and income supports.

Another major factor that has driven governmental agricultural policy is the desire to ensure affordable food. Once most of the agricultural land base of the United States had been settled, the most effective way to increase agricultural food supply (and, in turn, reduce prices) was to improve technology. This effort led the public sector (both federal and state) to continuously support agricultural research. However, farm groups (and their representatives) recognized that increased supply tended to reduce prices. As a result, additional policies aimed at supporting agricultural income implicitly became part of the compensation to farmers for enabling increased supply through publicly funded research (de Gorter *et al.*, 1992). The political bargaining between agricultural and urban groups led to coalitions that generated cooperative solutions aimed at sustaining farmers' welfare and expanding food demand through governmental food-assistance policies (such as food stamps and food aid to developing countries).

Naturally, the extent to which agriculture has been supported has depended on budgetary constraints and political–economic considerations (Rausser and Goodhue, 2002). The pressure to reduce support for agriculture may increase in periods in which the public feels growing concern about budget deficits and in which the political strength of agricultural lobbies is declining. The need to control costs and to respond effectively to natural variability thus caused the design of US agricultural policies to evolve over time.

Farm to Food Legislation

During the past 30 years, each successive 'farm bill' (the legislation that sets forth US agricultural policy) has reflected the public discourse of the day. For example, the Food Security Act of 1985 focused on loan programs, target prices, deficiency payments (the expected deficiency payment for a particular crop, c, is

$$E(d_{ct}) = \left[P_{ct}^{T} - \mathrm{Max}\left(P_{ct}^{S}, E(P_{ct})\right)\right](1-\omega_{ct})L_{ct}Y_{ct}$$

where P_{ct}^{T} is the target price; P_{ct}^{S}, the support price; $E(P_{ct})$, the expected average price received by farmers; ω_{ct} the percentage of land base required to be idled; L_{ct} the land base in period t; and Y_{ct}, the program yield per unit of the land base), acreage reduction, and public grain-stock reserves. The export provisions of the 1985 Act included food-aid and cargo preferences. Conservation provisions created 'sodbuster,' 'swampbuster,' and conservation reserve programs (CRPs), with the stated intent of removing highly erodible land and wetlands from production – and thus, indirectly, managing supply response (Rausser, 1992). The 1985 Act also authorized three alternative market-promotion programs and continued food-stamp programs. After the bill was passed, export subsidies from both the European Union and United States created a prisoners' dilemma global competition, with the net effect of decreasing world food-commodity prices as well as their volatility (Reagan, 1987).

By the end of the 1990s, it had become increasingly clear that any incremental improvement to the economic well-being of the US agricultural sector depended more on access to overseas markets than on domestic market demand. Accordingly, the flavor of public discourse resulted in a 1990 Farm Bill that particularly aimed to enhance exports. For the first time, this legislation included planning-flexibility provisions that promoted economic freedom by increasing farmers' ability to shift their resources in response to world market conditions. During this period (which coincided with the ongoing Uruguay Round negotiations), clear empirical evidence emerged that coupled-subsidy policies ultimately depressed market prices (Rausser, 1995).

In the political–economic process that shaped the 1996 Farm Bill (the Federal Agriculture Improvement and Reform Act), after the Uruguay Round had concluded, various commodity organizations and agribusiness interests coalesced in the hope of eliciting a more market-oriented agricultural policy. Partly as a result of these groups' influence, target-price deficiency payments were replaced by fixed 'production-flexibility contract payments' that would be paid during the ensuing 7 years, and both the crop-basis and the acreage-reduction programs were eliminated. For the first time, farmers participating in US government programs were allowed to make their own planning decisions free of government

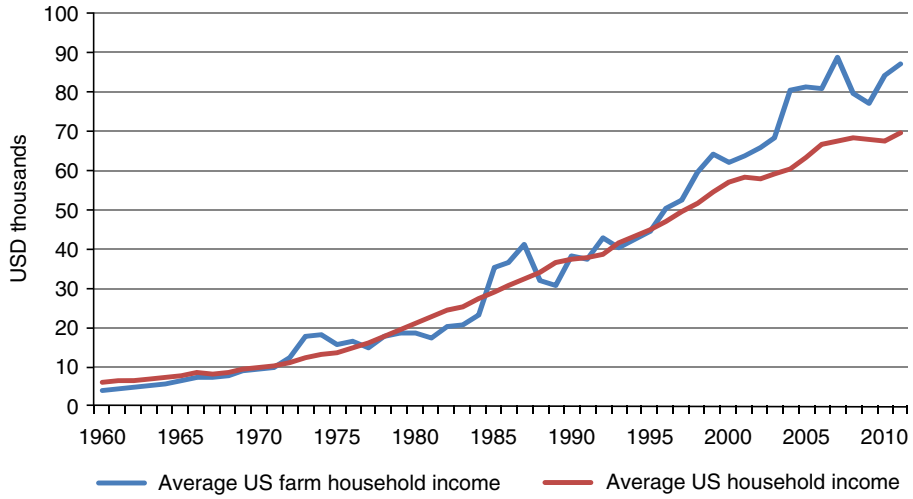

Figure 1 Mean US farm household income and mean US household income, 1960–2011. Reproduced from United States Department of Agriculture Economic Research Service, 2013. regulations (with minor restrictions). Meanwhile, many in the economics profession hoped that these 7-year payments would allow the US government to gradually terminate commodity-market subsidization.

Unfortunately, political–economic forces squelched this hope. The 2002 Farm Security and Rural Investment Act budgeted almost US$40 billion over a 6-year period for commodity programs and almost another US$10 billion for conservation. Accentuating the movement from legislation focused on agriculture to legislation focused on food consumption, more than 50% of the allocations made in the 2002 Act (US$149.6 billion) was directed to food stamps and other nutrition-title programs.

This trend accelerated with the passage of the 2008 Food, Conservation, and Energy Act. The Act renamed the federal 'food-assistance' programs the Supplemental Nutrition Assistance Program (SNAP). SNAP's nutrition subsidies accounted for more than 75% of the outlays for authorized programs under the Act, and the budget authority more than 5 years for this Act totaled US$284 billion. By the second half of 2012, 47.7 million Americans (more than 15% of the population) received benefits from SNAP. During the last survey (2010), average net monthly household income for recipients was US $336. Children included 49% of the recipients' households, and 20% included nonelderly disabled individuals (USDA, Center for Nutrition Policy and Promotion, 2011). Thus, farm-bill legislation had gradually become 'food-bill' legislation.

Nutrition legislation, such as SNAP, has provoked intense debate between congressional conservatives and liberals – so much so that it is not clear whether SNAP will survive in its current form. As budgetary concerns increase, some members of the Congress are trying to reduce SNAP funding by tens of billions of dollars (Nixon, 2013). Others have proposed to separate SNAP from the farm bill completely (Weisman and Nixon, 2013). Still other critics of SNAP assert that the assistance provided is not doing enough to enhance health and nutrition. Public concern about obesity may lend force to such criticisms (Guthrie *et al.*, 2007).

As the explicit purpose of US support to agriculture has changed from subsidizing farmers to subsidizing food programs, a simultaneous shift has occurred away from deficiency-payment policies toward crop revenue insurance programs. Deficiency payments provided farmers with insurance in the event of low prices but failed to protect them against variability in yields. To help farmers hedge against the risk of falling prices as well as variable yields, crop revenue insurance programs guarantee that farmers will receive minimum total revenues (based on acreage and historical average yields). As a result, crop revenue insurance has quickly become the most expensive agricultural subsidy in the United States, costing taxpayers nearly a trillion dollars over the past decade. Crop revenue insurance programs in the United States have a sizable subsidy component because without the subsidy, participation would be low. It is important to note that these policies tend to reduce agricultural efficiency (Goodwin and Smith, 2013).

Another factor in the development of US agriculture and agricultural policy is a continuous trend toward increasing automation, capital intensity, and size of agricultural operations. Partly as a result of this trend, the wealth gap between farmers and the rest of the population has continued to shrink; in fact, both the income and the wealth of agricultural households have recently exceeded those of US households generally (**Figures 1–3**).

The changing profile of American farms has weakened the rationale for supporting farmers financially (Gardner, 1992). The relative wealth of agricultural and nonagricultural households is largely sourced with steadily increasing land values (**Figure 4**). However, governmental support for agriculture continues unabated.

Empirical Consequences of Market-Distorting Policies

The two main types of policy that distort agricultural markets are controls on quantity (output quotas) and controls on price (price targets that result in deficiency payments). In general,

setting a fixed output quota benefits producers but harms consumers, because it triggers higher prices relative to the decreased supply, given the inelasticity of demand. In contrast, setting a price control (i.e., instituting price support) benefits both producers and consumers but hurts taxpayers, because they must pay the difference between consumers' and producers' prices in the form of deficiency payments (Alston and James, 2002).

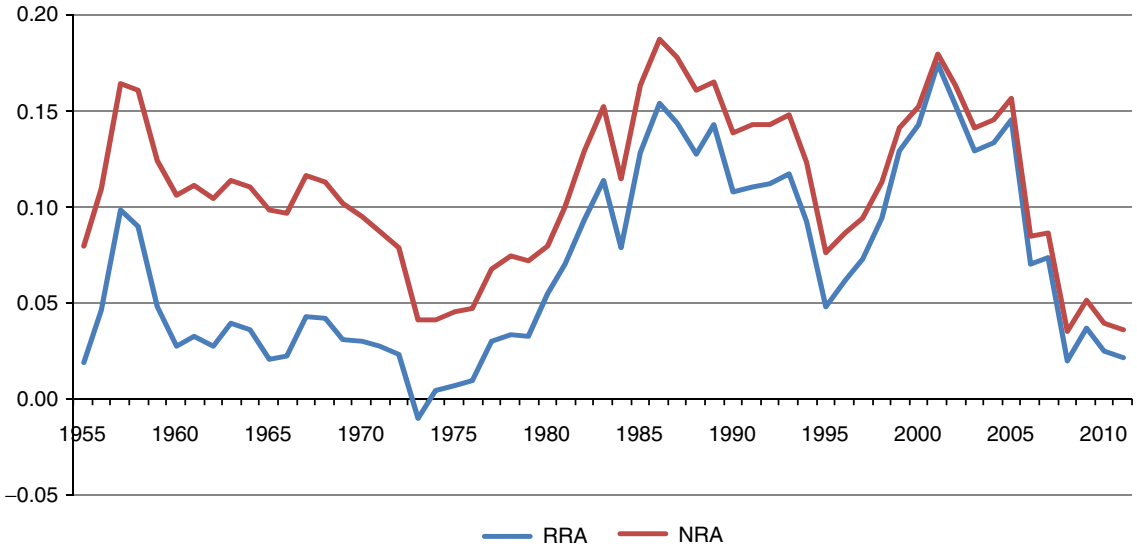

Figure 5 US RRAs and NRAs, 1955–2011. Reproduced from Anderson, K., Nelgen, S., 2013. Updated National and Global Estimates of Distortions to Agricultural Incentives, 1955–2011. Washington, DC: World Bank. Available at: www.worldbank.org/agdistortions (accessed 30.09.13).

The high levels of distortions to agriculture that result from government intervention have been recognized for decades. Recently, however, new and comprehensive data aggregated and synthesized by the World Bank (most recently by Anderson and Nelgen, 2013) have made it possible to analyze selected key metrics that quantify the impact of US agricultural policies. These statistics account for 77% of global output of the 30 most valuable agricultural products and represent 85% of global exports (Anderson *et al.*, 2013). The Nominal Rate of Assistance (NRA) reported by the bank approximates the governmental distortions that result in a gap between the current market prices and the prices that would exist in the counterfactual world of no governmental intervention (note that an NRA can be less than 0 if high export tariffs and farm taxes create a political environment in which the agricultural sector is stifled). The United States, of course, has had only positive NRAs in the last half-century (**Figure 5**).

Another, arguably more expressive, metric is the relative rate of assistance (RRA). It is calculated as follows:

$$\text{RRA} = 100 \times [(100 + \text{NRAag})/(100 + \text{NRAnon-ag}) - 1]$$

As it measures the percentage of a country's agricultural distortion relative to its nonagricultural market distortion, the RRA provides insight into a country's bias toward its farm sector (i.e., when RRA > 0, indicating that a country favors agricultural productivity) or against its farm sector (i.e., when RRA < 0, indicating that a country fails to stimulate agricultural productivity). As **Figure 5** suggests, when agricultural commodity prices were high in the United States (e.g., 1973, 2006, and 2009), RRAs were low. In contrast, during periods of low agricultural commodity prices (e.g., 1983–90), RRAs were high. Note that although agricultural prices have risen during the new millennium, rates of assistance have naturally fallen.

Traditionally, NRA and RRA levels increase with a country's per capita income; high-income countries have a positive agricultural bias and developing countries have a negative bias. However, in the last few decades, developing countries have shown a significant increase in their RRAs, so that the RRAs of both developed and developing countries are converging toward zero (**Figure 6**). This trend implies that less-distorting policy programs are generally being instituted.

The other two metrics that are important for understanding economic distortion caused by the government intervention are the welfare-reduction index (WRI; **Figure 7**) and the trade-reduction index (TRI; **Figure 8**). The WRI measures the welfare cost to consumers of these price distortions. As the WRI is related to the square of the deadweight loss wedge, it is always positive, whether the policy hurts or helps the agricultural sector. During periods of low commodity prices, when government subsidization has been substantial, high rates of welfare loss are evident. In recent years, however, increased openness of agricultural trade and the introduction of biofuels have led the welfare loss to decline.

Similarly, the TRI measures the percent change in trade volume caused by governmental policies, such as export tariffs and import caps (it could also be interpreted as the taxation amount that, if applied to all tradable agricultural products, would produce the same effect on trade). The 1980s, for example, was a period of high distortion and trade reduction (presumably, the government's goal at the time was to protect international prices of grain from further deterioration). In contrast, the new millennium has seen increased trade openness.

It is important to remember that the agricultural sector has unique subtleties, because the firm that owns the land is often not the same as the firm that operates the land. Landowners benefit the most from a system of price supports and output controls, as long as the output (or quota) certificates are issued to them, not to tenants. If the output certificates were issued to tenants, landowners would lose out, as the tenants, not owners, would receive any deficiency payments.

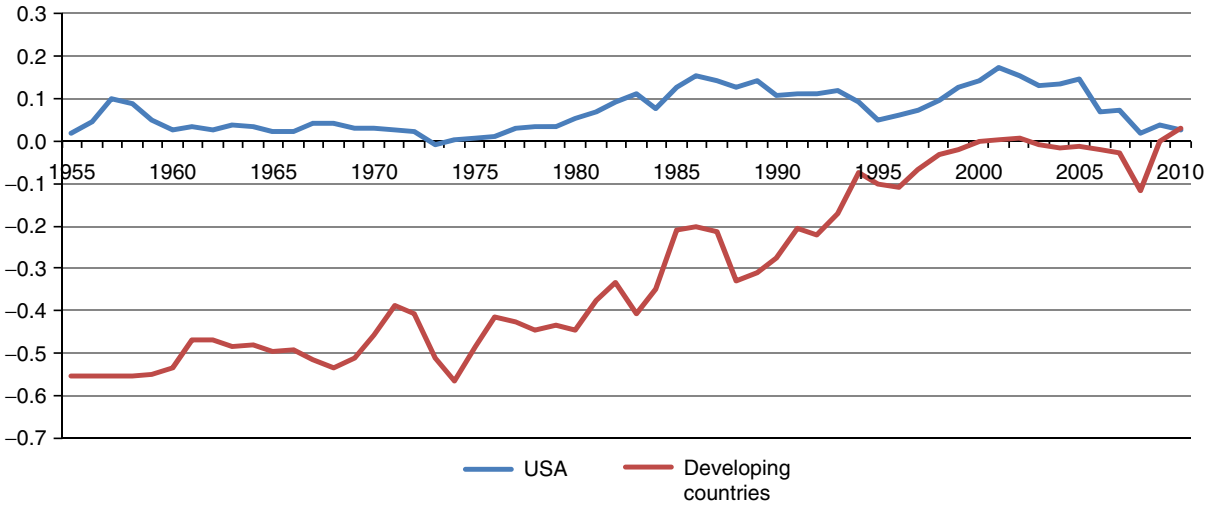

Figure 6 RRAs in the United States and developing countries, 1955–2011. Reproduced from the World Bank, 2013. Database for Distortions to Agricultural Incentives. Available at: http://go.worldbank.org/YAO39F35E0 (accessed 22.08.13).

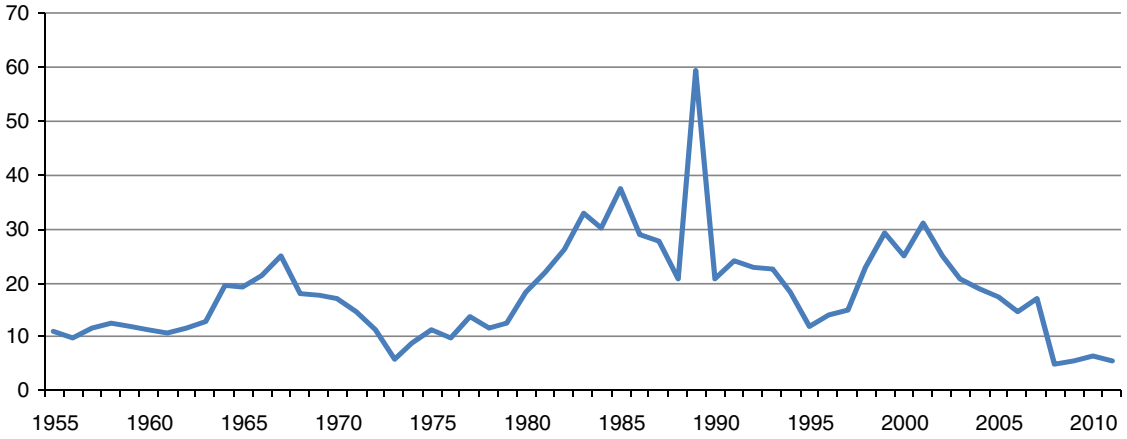

Figure 7 US WRI, 1955–2011. The WRI is related to the square of the deadweight loss wedge, so it is always positive, whether policies hurt or help the agricultural sector. Reproduced from Anderson, K., Nelgen, S., 2013. Updated National and Global Estimates of Distortions to Agricultural Incentives, 1955–2011. Washington, DC: World Bank. Available at: www.worldbank.org/agdistortions (accessed 30.09.13).

Even without output controls, landowners still benefit under price controls (price support). However, they would be adversely affected by acreage control or land set-asides. In contrast, tenants of agricultural land would be worse off under the dual price support–output control system than under no regulation, unless output certificates were issued to them rather than to landowners. Meanwhile, owner-operators of agricultural land who hire labor benefit under output controls because of their overwhelming land share compared with labor share. However prospective farmers trying to enter the industry, who often possess neither land nor capital, would be discouraged by both price support and output controls, as such measures would make agricultural land more expensive and thus create barriers to entry (Floyd, 1965). Price support or output controls favor preexisting farmers who captured the initial land rents that resulted from historical governmental intervention.

Unintended Consequences of US Agricultural Policies

Over the years, US agricultural policy interventions have resulted in significant unintended consequences. These consequences include periods in which the government has held large stores of agricultural commodities, variable input resources have been overallocated, and world food-commodity prices have been depressed. To relieve the pressures of excess supply, the US government has attempted to expand demand via programs such as foreign food aid, domestic food-stamps, export subsidies, and the USDA's Foreign Agricultural Service's export enhancements. The voluntary nature of these programs has allowed participants to gain access to governmental subsidies as long as they honor crop-acreage-base restrictions, acreage-idling programs, and conservation measures.

One of the most significant unintended consequences of US policy has been to create and exacerbate booms and busts

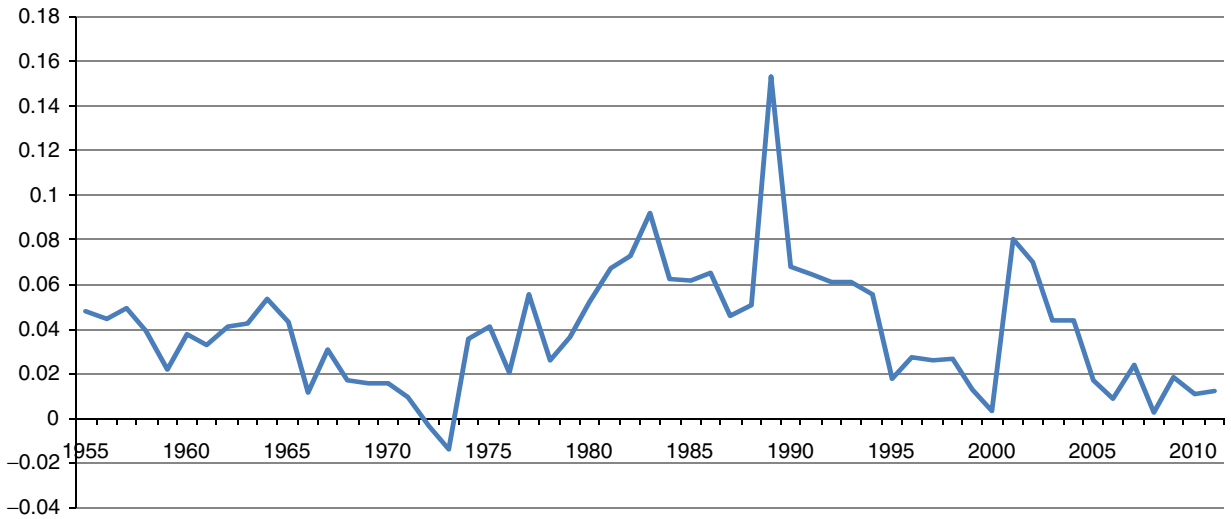

Figure 8 US TRI, 1955–2011. Reproduced from Anderson, K., Nelgen, S., 2013. Updated National and Global Estimates of Distortions to Agricultural Incentives, 1955–2011. Washington, DC: World Bank. Available at: www.worldbank.org/agdistortions (accessed 30.09.13).

in domestic and global commodity markets. Such commodity booms and subsequent busts are clearly exemplified in the early 1970s and again in 2008. Following shocks to either demand or supply (or both), market structures themselves tend to be the sources of these booms and busts. For example, in the 1970s, a huge outward shift in commodity export demand caused a spike in commodity prices. Similarly, in 2008, sharply increased demand for grains resulting from a huge increase in US biofuel production drove grain prices upward quickly.

Another major factor in commodity price fluctuation is stockholding. Both the 1970s and the 2008 price boom were directly preceded by the lowest levels in years of inventories of corn, wheat, and rice. These very low inventories help to explain the high volatility of commodity prices in the 1970s and in 2008: no stockpile could be drawn from to increase supply when needed. One early attempt to solve this problem failed: in the early 1970s, the US government started to print more money in the hope of inflating away the high real price of energy (Carter *et al.*, 2011). This increase in the supply of money simply drove prices higher, showcasing how macroeconomic linkages can cause price spikes in commodities across the board.

The varied effects of US monetary and fiscal policies, in combination with US agricultural policies, resulted in greater volatility of food-grain and livestock prices, with booms in the 1970s and busts in the 1980s. Booms can result from the 'overshooting' phenomenon, which was traced to the flex-versus-fixed-price dichotomy of Okum and Dornbusch (Rausser *et al.*, 1986). In particular, the disequilibrium in money markets caused disequilibrium in commodity-storage markets and exchange-rate markets. Economists recognized that both of these phenomena helped explain the price spikes that had taken place throughout the 1970s. In contrast, during the 1980s, the disequilibrium in money markets and exchange-rate markets ran in the opposite direction, forcing volatility on the downside for a number of food-commodity markets. Had it not been for government market-subsidy programs, the agricultural financial crisis of the mid-1980s would have been even more dramatic (Rausser *et al.*, 1986; Foster and Rausser, 1991).

The intricacies of cross-commodity linkages also can often conceal forces that drive price booms and busts. For example, high-energy costs during the 1970s and in 2008 more than doubled the cost of many fertilizers used as agricultural inputs, so that booms in agricultural commodity prices were inevitable (Carter *et al.*, 2011). Historically, short-term policy responses to supply shortages have exacerbated such problems and caused even larger price spikes. In one instance, after the former Soviet Republic bought 30 million metric tons of grain from the US in 1972, a domestic shortage of grains and soybeans occurred. To decrease demand sufficiently to mitigate the shortage, the federal government created an export embargo on soybeans in 1973. Although this measure worked in the short term, farmers were forced to sell at such low market prices that they had little incentive to increase soybean production. The resulting impacts helped Brazil displace the United States as the largest producer of soybeans (Carter *et al.*, 2011).

Other Forms of Intervention

Public Investment in Research and Development

Publicly funded research and development (R&D) has been a crucial component of the federal government's expenditures benefiting US agriculture as the Morrill Act secured land grants for public research institutions. The steady increase in public R&D (**Figure 9**) contributed to the sustained increases in agricultural productivity that occurred in the second half of the twentieth century.

In the United States, the complementarity between public-good R&D and commodity-based subsidization largely account for the huge productivity increases in food-commodity production (Rausser, 1992; de Gorter *et al.*, 1992). The federal

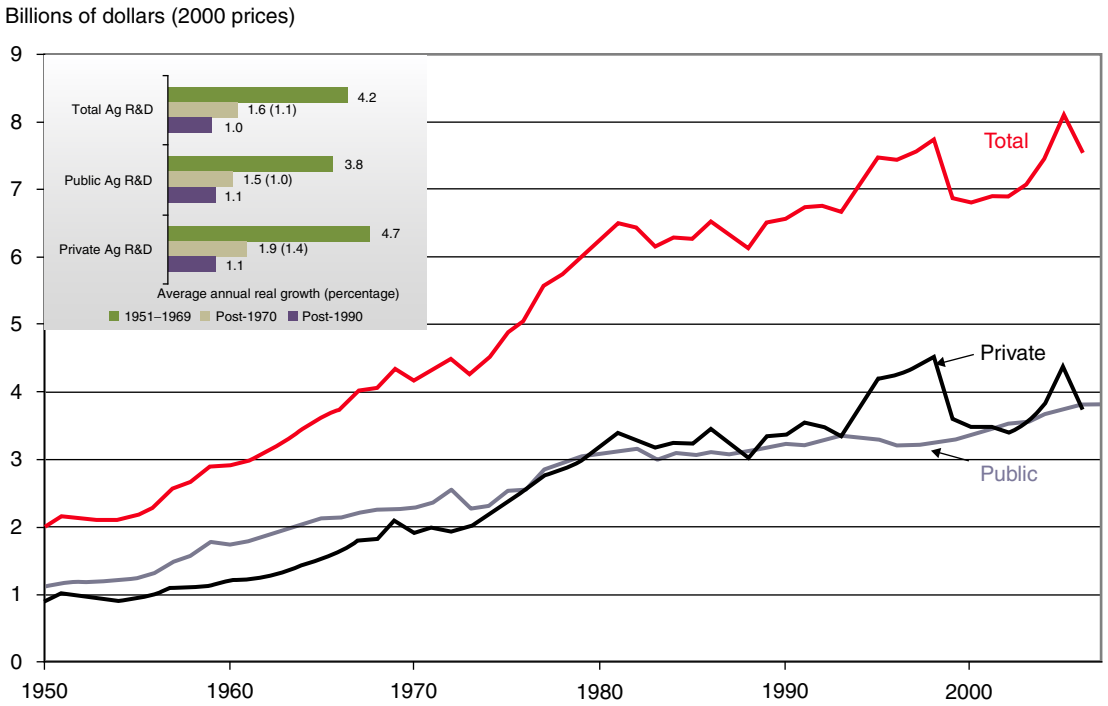

Figure 9 US agricultural R&D expenditures, 1950–2007. Reproduced from Pardey, P.G., Alston, J.M., 2012. Global and US trends in agricultural R&D in a global food security setting. In: Improving Agricultural Knowledge and Innovation Systems: OECD Conference Proceedings, pp. 19–40. Paris and Washington, DC: Organisation for Economic Co-Operation and Development.

and state support of land-grant universities and public-good R&D, along with the support of cooperative extension, has been instrumental in expanding supply response to both market- and governmental-based incentives. This joint complementarity between public-good R&D and commodity subsidization has been theoretically demonstrated on numerous occasions (Innes and Rausser, 1989; Foster and Rausser, 1993; Rausser and Foster, 1990). Keeping everything else constant, the complementarity of these two policies has reduced the price volatility that would otherwise have occurred and depressed market price levels, especially when price supports were abandoned and replaced by target prices and deficiency payments (the expected deficiency payment for a particular crop, c, is

$$E(d_{ct}) = \left[P_{ct}^{T} - \mathrm{Max}\left(P_{ct}^{S}, E(P_{ct})\right)\right](1-\omega_{ct})L_{ct}Y_{ct}$$

where P_{ct}^{T} is the target price; P_{ct}^{S}, the support price; $E(P_{ct})$, the expected average price received by farmers; ω_{ct}, the percentage of land base required to be idled; L_{ct}, the land base in period t; and Y_{ct}, the program yield per unit of the land base). In the final analysis, the combination of research and subsidization policies is largely responsible for the relatively low ratio of food expenditure to income in the United States versus that of many other countries.

Environmental Intervention

As concern for environmental amenities has increased, environmental conservation has become an increasingly important element of agricultural policy in the United States. The expansion of agriculture to environmentally sensitive areas and the damage to ecosystems and water sources caused by agricultural activities have spurred legislation designed to mitigate such effects. One type of legislation, for example, has restricted agricultural activities in environmentally sensitive areas. Such land-use restriction has been introduced not only to lessen environmental hazards but also, as previously noted, as a means to control agricultural supply.

Historically, nonvoluntary regulation has been the method of choice in industrial settings when it comes to environmental policy. However, in the agribusiness sector, the United States has heavily favored conservation policies called 'payment for environmental services' (PES) programs. These PES programs adopt a voluntary approach to environmental conservation in sectors where firms do not explicitly reap the benefits of conservation themselves and have no incentive to conserve without some external motivation. Originally, such agricultural conservation programs came in the form of payments to farmers for letting arable land lie fallow after the Great Depression, in order to maintain adequate soil quality and avoid another Dust Bowl.

Fifty years later, the institution of the CRP by the Food Security Act of 1985 marked a turning point for conservation efforts. The CRP constituted an effort to protect wildlife and to improve water and air quality as well as to mitigate soil erosion. Although the PES programs began by diverting land from agricultural uses, many CRP programs applied to working lands. In 1985, cross-compliance requirements were introduced requiring that both land-diversion and working-land measures be undertaken in order for a farmer to be eligible for income-support programs (Claassen *et al.*, 2008). A decade later, another environmental policy, the Environmental

Quality Incentive Program, was introduced. It subsidizes investments in animal-waste management that meet environmental objectives. Government-support programs continue to reflect concern for the environment, and environmental support programs are looked upon favorably by the World Trade Organization.

Biofuel Policies

The 2008 farm bill, for the first time, included incentives for energy production and explicitly connected the agricultural and energy industries at their nexus: biofuels. Although the biofuel provisions were a minimal budgetary line-item in the 2008 bill, they should be viewed in the context of the renewable-energy legislation that was enacted at the same time, which also promoted biofuels. From the standpoint of US agricultural interests, the most obvious motivation for instituting these biofuel policies was that they would allow agricultural producers to receive advantageous prices for corn, oilseeds, and perhaps even wheat. Biofuel policies also held out hope that taxpayers would be relieved of the burdensome commodity subsidies (deficiency payments) paid to agricultural producers. In fact, the legislation worked exactly as expected. Increased demand for corn and other biofuel inputs raised prices and lowered deficiency payments. It also caused US ethanol production to increase sevenfold (Rausser and de Gorter, 2013).

The federal government supported the introduction of biofuels by mandating that a minimum percentage of fuel used for transport be biofuel. This mandate connected agriculture more closely to energy, with the result that another set of forces began to influence food-grain price volatility. A 2007–08 commodity price boom correlated closely with a boom in crude-oil prices. Though the energy-policy arena had been saturated with biofuel mandates since 2006, only tax credits for ethanol fuel blenders explicitly linked corn prices to ethanol prices (Rausser and de Gorter, 2013). Thus, in order to gain a comprehensive picture of food-grain commodity volatility and pricing, one must look not only at agricultural and macroeconomic policy but also at environmental and energy policies (the interdependency of agricultural and environmental policies and the need to coordinate policy design were recognized early by Lichtenberg and Zilberman, 1986). The potent effect of the 'ag-energy' legislation becomes clear when corn prices before and after the legislation's adoption in 2008 are compared. In 2005–06, the lower bound on corn price was US$1.75 per bushel. In 2009–10, the lower bound did not drop below US$3.21 per bushel. In just 4 years, the price of corn increased to more than 80%.

Food Quality and Ecological Farming

Concerns about both nutrition and the environment have been on the rise in recent years in the United States. These concerns have brought new participants into the debates about agriculture, especially people interested in organic farming and other ecological practices. Originally, US organic certification was voluntary: farmers who wanted to certify their products as organic could apply to industry associations and, if they met certain requirements, receive certification. More recently, however, organic certification has become a strictly regulated, government-supported process. More than 50 certification agencies and a USDA organization called the National Organic Program now oversee the multibillion-dollar organic farming industry.

One of the big questions regarding the future of organic farming is whether it will include genetically modified (GMO) crops. Traditional supporters of organic farming have been very public about their opposition to GMO crops (Freedman, 2013). However, some scientists have argued that a symbiosis between organic agriculture and plant genetics will be able to meet future nutritional demands and also address environmental concerns (Ronald and Adamchak, 2010; Bennett and Jennings, 2013). Nonetheless, a vocal contingent of the organic-food and sustainable-farming movement seeks to reduce public support for agricultural commodities and restore traditional agriculture because this contingent is concerned about the long-term effects of genetic monocultures (a spokesperson for this movement is Michael Pollan, author of the bestsellers The Omnivore's Dilemma and In Defense of Food). However, critics of this movement assert that such proposals will make food more expensive, to the disadvantage of low-income consumers. For this reason alone, they argue, supporting efficient, high-yield farming remains vital. Still other food-policy experts maintain that these debates rest on the false premise that industrial and organic farming are mutually exclusive alternatives. They maintain that both types of agriculture have established their own markets and that this pluralistic approach to agriculture can satisfy diverse needs.

Policy Making and the Changing Political–Economic Landscape

In the current century, the US – and the world – has shifted from chronic excess supply caused by growing farm productivity to chronic excess demand and rising real food prices. The reasons for the shift include increasing demand for food as income grows (especially in Asia and other developing regions) and increased consumption of meat. Raising meat animals for human consumption entails producing significant amounts of grain, introducing biofuel, and slowing growth in agricultural productivity (Zilberman *et al.*, 2013). Changing political conditions have also led to increased demand for nonfood uses of agricultural crops. In particular, as it was suggested, rising energy prices and increased public concern about climate change, environmental sustainability, and energy security have increased opportunities to produce fuel from agricultural crops (Zilberman *et al.*, 2013).

As energy uses constitute a new source of demand for agricultural commodities and have much higher price elasticity than does food demand, demand for biofuel crops can elicit increased supply without generating significant price erosion. Corn-based biofuel was first introduced in the United States as a food additive, but corn-ethanol production drastically increased when fossil-based fuel prices almost doubled, between 2004 and 2007. Biofuels and the rising food prices associated with them even contributed to accumulation of

wealth in the farm sector: prices for agricultural land continued to grow even when other real estate prices were on decline, accentuating the shift of relative resource allocation toward the farm sector relative to the rest of the economy (Figures 1–3).

Since 2007, however, public concern about the impact of corn-ethanol production on food prices has led to the imposition of limits on the amount of corn-ethanol mandated (Rajagopal *et al.*, 2007). Furthermore, the demand for corn ethanol has been constrained by the 'blend wall' (the limit on the proportion of ethanol that can be used by gasoline engines). The US government has, therefore, mandated that a second generation of biofuels be developed, preferably from nonfood products that compete only minimally for land and other resources with agricultural food production.

Despite attempts within the federal government to mitigate harmful effects of biofuels on world food prices, the agricultural sector's political muscle has been sufficiently strong to secure continued support for traditional or agricultural commodities program. Agriculture continues to become more capital intensive and uses a diminishing share of labor, so that farms are becoming fewer in number but larger in size. This transformation makes it possible for these fewer but larger entities to become a more cohesive and politically effective group. Furthermore, the introduction of biofuels has motivated some of the major multinational oil companies to join the agricultural policy debate. Some of these companies may oppose mandates for second-generation biofuels that could reduce oil prices.

Although a movement to reduce unconditional transfer of income to the agricultural sector has recently gained traction, the net effect of this trend is debatable, as public resources are increasingly being invested instead in crop-insurance programs. However, as the average household income grows and interest in environmental issues expands, environmental groups exert greater influence on agricultural policies. Some environmentalists support biofuel policies, as do biofuel producers, automakers, many fuel transporters, the energy-security community, and certain growers' associations. Even some environmental groups that opposed tax credits and tariffs now seek to retain mandates. However, other groups are coalescing in opposition to mandates, tax credits, and subsidies. As ethanol policies support food-grain markets through higher prices, groups such as livestock, dairy, and poultry producers are beginning to form organized opposition to continued support for ethanol producers. So are food processors that no longer enjoy the low market prices that traditional agricultural policies supported (one example of these new interest groups is BalancedFoodandFuel.org, whose members include various meat, livestock, poultry, and dairy producer associations (Hahn, 2008)).

In summary, the landscape of organized interest groups that seek to influence the US agricultural policy continues to change at an increasingly rapid pace. The 'iron triangle' that once shaped governmental intervention in commodity markets has expanded into an 'iron maze' of organized environmental, energy, consumer, and agricultural interest groups. To complicate matters, at least three executive-branch agencies (the Department of Energy, the USDA, and the Environmental Protection Agency) also play significant roles. What remains to be to be seen is whether such changes can lead to less distorting and expensive policies.

Glossary

Biotechnology Use of genomic-based technologies that include identifying the genetic code of important genes, the following of traits by tracking DNA sequences flanking the gene(s) controlling the trait, and the molecular transfer of genes known as genetic engineering.

Genetic resources The array of inherited traits present among various accessions of the organism. Selection and breeding of new varieties depend on the available genetic variation represented among the available genetic resources.

Germplasm The collection of various genotypes available for breeding programs.

Immunodeficiencies Immune system compromises due to the lack of various factors, including Vitamin A.

No-till cropping system Direct seeding into undisturbed or minimally disturbed soil seed beds, thus reducing environmental degradation of soils and saving time and cost of tillage.

Population monster A term used by Norman Borlaug to indicate that the human population is increasing so fast that maintaining sufficient food is nearly impossible.

Semidwarfness Crop plants with shorter stature compared to common varieties. Generally, the reduction in height of perhaps 30% leads to a shorter and stronger stem that can hold more grain and not fall over due to the weight.

Stem rust A fungal disease that can cause serious losses of yield in certain small grains. The organism can mutate and become virulent on new varieties, such as the new strain called Ug99.

Father of the Green Revolution

If the word 'Green' is entered in Google, the term 'Green Revolution' does not appear in the list of sites – at least not in the first 30 pages of Google listings. Terms such as Green Building and Leadership in Energy and Environmental Design scorecards, the Green Party, Energy and the Environment, Sustainable Living, Green Chemistry, Green Colleges, Green Hotels, Greenpeace, and even the Green Bay Packers appear without a mention of the Green Revolution. Many people have heard of the Green Revolution, but few have heard the name of the 'Father of the Green Revolution,' Norman E. Borlaug. This is in contrast to what one would expect because he was one among the five people to receive the Nobel Peace Prize (Borlaug, 1970), the National Medal of Freedom, and the Congressional Gold Medal. The other four were Martin Luther King, Mother Teresa, Nelson Mandela, and Elie Weisel. From the time when Borlaug was awarded the Congressional Gold Medal in 2007, two others have received this trifecta of awards, namely, Mohamed Yunis and Aung San Suu Kyi. Norman Borlaug died at the age of 95 in 2009 and had lived an active life up to the time of his death, contributing to a more food-secure world (Vietmeyer, 2008, 2009, 2010, 2011; Phillips, 2009). Although most developed countries had sustained food surpluses by 1950–2000, developing countries were and still are under the threat of starvation.

Why do so few people know about Norman Borlaug? One would think that receiving more important awards than other famous people would make his name a household one. It has been stated that Borlaug saved the lives of more people (approximately 1 billion) than anyone else who has ever lived through his wheat improvement efforts and his persistence in convincing other countries to use the new seed, especially India and Pakistan (Borlaug, 2007). Borlaug's name is recognizable by many residents of South Asia, with his efforts being taught in their school history classes.

Defining the Green Revolution

So, what is the Green Revolution? The term was coined in 1968 by the U.S. Agency for International Development Administrator William Gaud and encompasses many aspects, but essentially involves the breeding of high-yielding crops that positively respond to fertilizers and irrigation. The crops that led the Green Revolution were wheat and rice. Henry Beachell bred rice at the International Rice Research Institute (IRRI) in the Philippines in ways that were similar to those by Borlaug when he bred wheat at the Center for the Improvement of Maize and Wheat (Spanish acronym 'CIMMYT') in Mexico. A key feature was to shorten and strengthen the stems (straw) such that the plant could bear more grain without falling over; it is difficult to realize the gain in yield when the heads of grain are on the ground. This shortening of the stem was the result of bringing in genes for 'semidwarfness' that allowed the plant to make good use of fertilizer and water in producing higher recoverable yields. Borlaug also bred for resistance to wheat diseases such as the devastating stem rust. This disease was a serious problem but was largely overcome by the discovery of resistance genes and breeding them into the new varieties. However, in 1998 a new strain of stem rust was detected and reported in Uganda (known as Ug99). Borlaug sounded the alarm because he knew that 80–90% of the world's wheat varieties are susceptible to this strain, and the pathogen was spreading to other countries. A huge effort was mounted to develop resistant varieties, largely funded by the Bill & Melinda Gates Foundation. Several varieties are now available for Africa with a reasonable degree of resistance to Ug99. This virulent strain is yet to reach the United States; however, various major wind currents will probably bring it there before too long. The Green Revolution technology has been extended to many other developing-country crops, including sorghum, millet, maize, cassava, and beans.

Borlaug developed a strategy whereby he utilized two locations for breeding. One was near sea level at Ciudad Obregon in northern Mexico and the other was near his home base of CIMMYT at nearly 2000 m elevation. The purpose for having nurseries in two distinct locations was to obtain two generations per year, thus presumably allowing greater progress in making crosses and selecting for yield. What he did not know was that many of the selections that were impressive at both locations would respond well in diverse environments around the world, specifically in locations with very different lengths of the day. This trait was called 'photoperiod insensitivity.' These selected varieties yielded well in Mexico as well as in faraway places such as India and Pakistan. In fact, the Borlaug varieties responded so well that Mexico soon did not have to import wheat to feed the population – and the same came true for India.

Food Production versus Human Population

Before the Green Revolution-varieties were developed, the world had almost lost hope that anything could stave off the starvation and death of millions of people due to production of food crops not keeping up with the increase in population. In fact, Paul Ehrlich (1968) had published a book called the 'Population Bomb' in which he indicated that the battle to feed the world had been lost. This was probably a reasonable prediction; few people, if any, would have predicted that technology would provide the food needed to keep so many people alive. Remember, for example, that rice still feeds half the world. Keeping up the yield of rice and wheat is essential in providing sufficient food even today. The world population is now more than 7 billion people, reflecting a rate of adding 1 billion people to this planet every 14 years. Clearly, there is a major challenge ahead for agriculture to produce sufficient food in order to meet this 'population monster' (Borlaug's term). Even in his Nobel Peace Prize speech, Borlaug stated that there must be a push for increased food production for population control to be successful. One of the criticisms of the Green Revolution is that increased amount of food led to overpopulation worldwide. Some people subscribe to the Malthusian theory that population growth will increase to an extent where food production cannot cope with and widespread deaths will inevitably occur (Malthus, 1798) (**Figure 1**).

The population of the world increased from 1 billion to 2 billion from 1804 to 1927 (123 years). The last increase of 1 billion people occurred in just 14 years. The current population of over 7 billion will increase to approximately 9 billion by 2050. One way to buy some time in order to balance the relationship of population growth and food production is to have population control. The length of time to double the human population depends on the rate of population growth. As can be ascertained in **Figure 2**, a reduction from a 4.0% rate of population increase to a 1% rate changes the years required to double the population from 18 to 70 (Conway, 2012).

China currently has the highest population of any country (1.3 billion); however, the rate of population growth has been slowed by the one-child policy enacted in 1979. India (1.2 billion in 2011) will probably surpass China in population during the next two to three decades.

Malnutrition

Why did Borlaug receive the 1970 Nobel Peace Prize? The Nobel committee was most likely trying to make the same

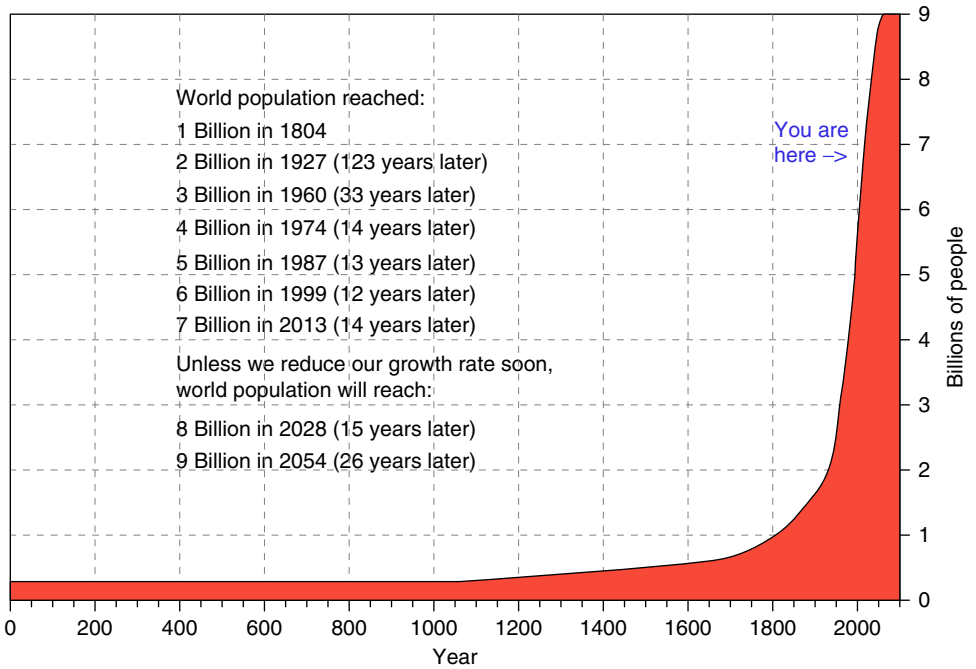

Figure 1 Past and future human population numbers. Reproduced from United Nations, Population Prospects; The 1998 Revision (United Nations Population Division, Department of Economics and Social Affairs).

Rate of population increase	Years required to double population
0.01%	6930
0.1%	693
0.5%	139
1.0%	70
1.5%	47
2.0%	35
2.5%	28
2.8%	25
3.0%	23
3.5%	20
4.0%	18

Figure 2 Years required to doubling population relative to rate of population increase.

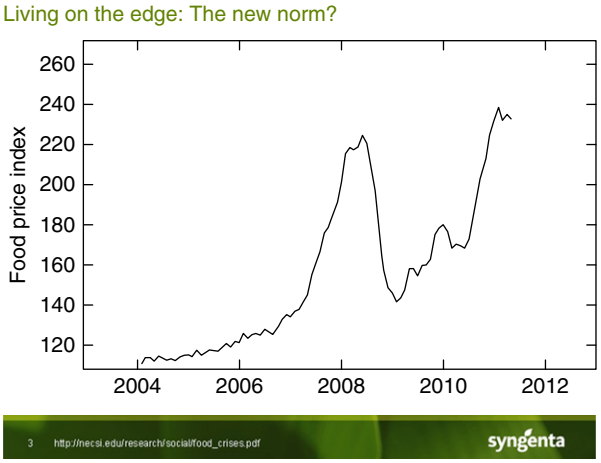

Figure 3 Food price spikes (2004–11). The FAO defines the Food Price Index as a measure of the monthly change in international prices of a basket of food commodities. It consists of the average of five commodity group price indices (representing 55 quotations), weighted with the average export shares of each of the groups for 2002–04.

point that Borlaug had always believed, that "You could not have peace on empty stomachs and human misery." Borlaug also believed that "Food is a moral right." One of the problems of malnourishment is that, if a child does not die due to starvation, he or she is still affected for the rest of the life due to poor early-brain development. Stunting in children is common when food is in short supply; this is not something that is readily corrected by providing sufficient food later in life. A country with malnutrition has a populace that is less productive. We have known for many years that diet is linked to immunodeficiencies. Malnutrition increases the occurrence of intestinal infections and diarrhea. The gut in healthy people has thousands of microorganisms (more microbes than cells in the whole body); malnutrition alters this microbial community and affects the transport of nutrients and the occurrence of inflammation (Icue and Powrie, 2012).

The link between nutrition and agriculture is now being recognized more than ever before. The World Health Assembly recently set a goal of reducing the number of stunted children by 40% by 2025 (Swaminathan, 2012). Hunger, therefore, is not just a matter of insufficient food. Deficiencies in the diet of zinc, iron, iodine, vitamin A, and vitamin B12, for example, all lead to malnutrition. This condition has been called 'hidden hunger.' Many believe that not being chronically hungry is a fundamental human right. It is recognized that intervention programs need to be available for the first 1000 days of life, from pregnancy to 2 years of age. Having new food-crop varieties genetically enriched in these important micronutrients is an efficient way to intervene. The Green Revolution also indirectly assisted in providing better nutrition, especially in Asia via increased income that allowed people to have a more diversified diet, including the consumption of meat, vegetable oils, fruits, and vegetables.

Importance of a Reliable Food Supply

Food security has become a major issue. As the price of food staples went up during 2008 due to shortages in storehouse levels of grain, there were food riots in at least 30 countries. Grain warehouses often needed to be guarded because of people stealing bags of grain. Figure 3 shows the spike in prices in 2008 and 2011. Figure 4 shows when food riots occurred in various countries; the striking coexistence of price with food riots.

Because of the importance of food production, Borlaug asked the Nobel Prize Committee to fund a Nobel Prize in Agriculture. After reviewing the 'last will and testament' of Alfred Nobel, the committee along with their legal counsel decided that such a Nobel Prize in Agriculture was not within the realm of the will. Undaunted, Borlaug and others established in 1986 the World Food Prize (considered by many as the Nobel Prize in Agriculture). This annual award provides US $250 000 to the winner(s). The World Food Prize Foundation also sponsors the Global Youth Institute to expose high school students from the US and abroad to opportunities in meeting world food needs. This youth institute was also Borlaug's dream. Although he had only one Ph.D. graduate student, he trained hundreds of young people from around the world. These students, who he called 'Hunger Fighters,' carried the technology and the philosophies back to their home countries. Borlaug believed in advanced technology, including biotechnology, to maximize yields. He also believed in the education of young people. Yet another unique feature of Borlaug's approach was to address political barriers to food production by telling his story and seeking government help in utilizing new technologies.

India was facing mass famine in the 1960s. Fortunately, Borlaug was invited to India by the Minister of Agriculture M.S. Swaminathan. Together with the Ford Foundation and the Indian government, wheat seed was imported from CIMMYT and first grown in the Punjab area. The results were dramatic and India augmented its program on plant breeding, irrigation, and agrochemicals. Based on these successes, India soon started using the new so-called 'Miracle Rice' labeled IR8, developed at IRRI, which had been established in 1960 in Los Banos, Philippines, by the Ford and Rockefeller Foundations along with the Philippine government. Peter Jennings, Sterling Wortman, Akira Tanaka, and Hank Beachell developed IR8 by

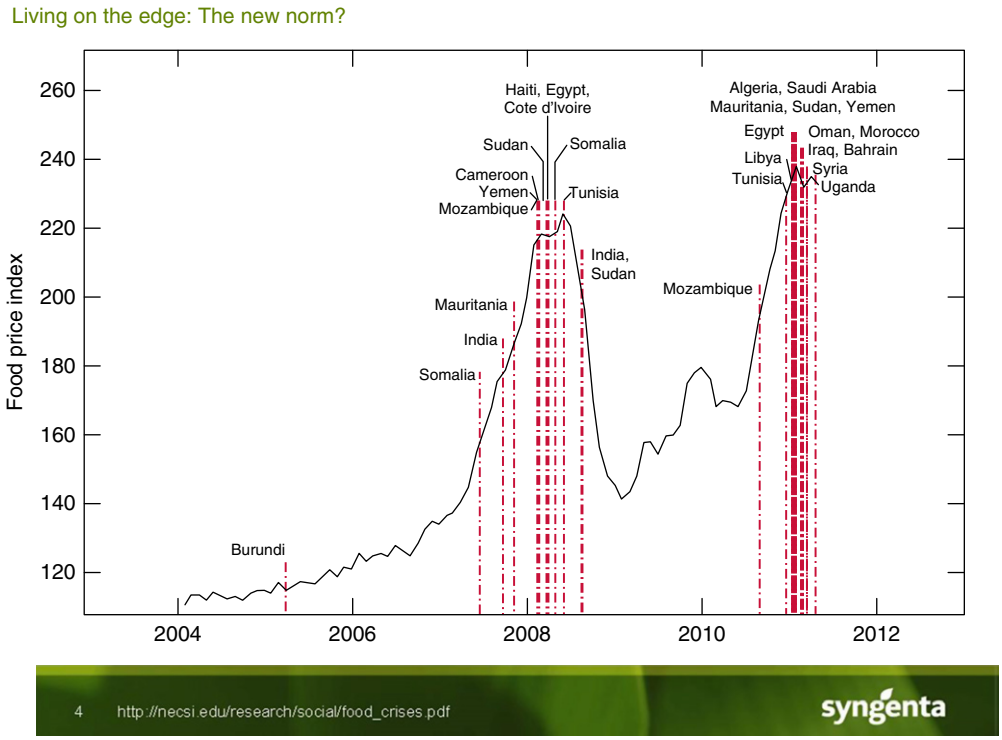

Figure 4 Food riots correlated with changes in the food price (2004–11) shown in Figure 3.

crossing a tall variety from Indonesia (Peta) with a short Chinese variety called Dee-geo-woo-gen. The high yield of what became known as IR8 was first recognized by IRRI scientist S.K. De Datta. The yield of this rice was ten times that of traditional rice. The Philippines also switched to IR8 and became a rice exporter. IR8 was released in 1966, which was the time that Borlaug's wheats reached India (Dar, 2012)

The 1970 Nobel Peace Prize to Borlaug signaled the importance of what was happening in agriculture. The new varieties were being rapidly adopted by farmers. Approximately 75% of the rice in Asia, half the wheat planted in Africa and more than half in Latin America and Asia, and 70% of the corn worldwide were new varieties. Some reports estimate that 40% of the farmers in the developing world were using the new varieties by the 1990s. The production of wheat in Pakistan, for example, increased from 4.6 million tons to 8.4 million tons from 1965 to 1970, almost doubling in 5 years. India's production went from 12.3 million tons to 20 million (Lobb, 2003). Countries other than Pakistan, India, Mexico, and the Philippines also benefited from the Green Revolution, namely, Afghanistan, Sri Lanka, China, Indonesia, Iran, Kenya, Malaysia, Morocco, Thailand, Tunisia, and Turkey. By the year 2000, more than 60% of the rice in developing countries had been generated by the research institutes.

Green Revolution in Africa

The Green Revolution largely missed Africa. Several reasons have been given for this situation; these include the infertile soils of Africa, uncertain rainfall, the lack of agricultural technology, the need for quality seeds, limited investment in irrigation, poor roads, immature markets and high transportation costs, the requirement for more information and know-how, and probably corruption and lack of political will among the countries. Clearly, improvements in any of these areas would have a positive impact. Kenneth Quinn, former Ambassador to Cambodia, has noted that the growing of miracle rice IR8 followed the development of roads that reduced the cost of moving fertilizers and other inputs to the farms and enhanced the ability to move the rice to markets. Several government agencies, nonprofit organizations, universities, and agricultural companies have now seized the opportunity to help in Africa. The countries of Africa are finally realizing the importance of putting more of their GDP toward agricultural goals. Malawi is a good example where the government developed a highly successful Agricultural Input Subsidy Program to assist smallholder farmers to obtain nitrogen fertilizer and maize seeds. A new African rice called NERICA (New Rice for Africa), derived from an African species of rice, has the potential to provide substantial yield increases. The food crisis in several African countries is being addressed through a program called Sasakawa-Global 2000. Norman Borlaug and former President Jimmy Carter were involved in the development of this program.

Poor infrastructure of a country contributes to its demise in terms of getting inputs to the farm and products to the market. In Africa, the larger markets are often many hours away (Figure 5).

Is the Green Revolution a Myth?

With all the positive aspects of the Green Revolution, why are some saying that its success is a myth and not sustainable?

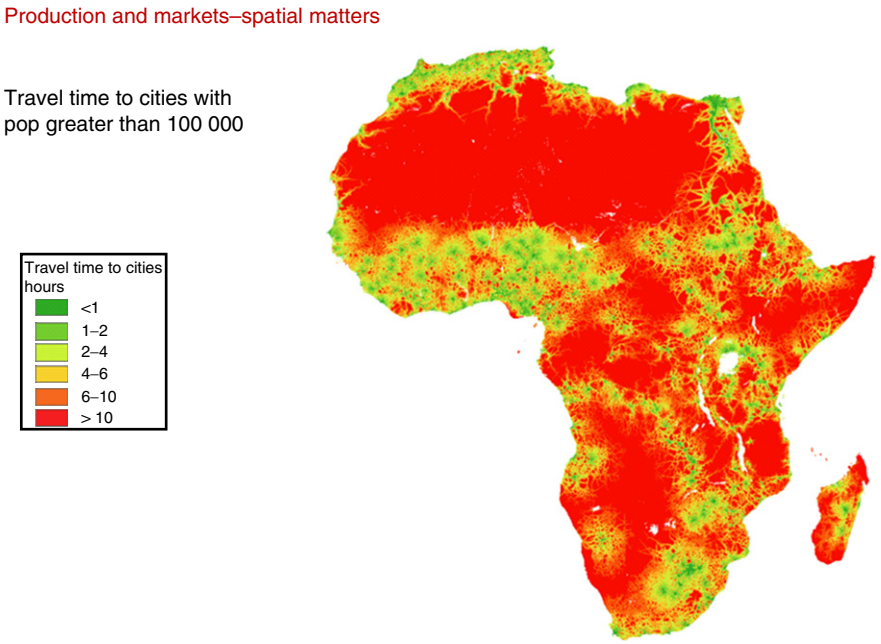

Figure 5 Time (travel) to move product from farm to market in Africa. Reproduced from Harvest Choice/Joint Research center of the European Commission. Available at: http://harvestchoice.org/topics/market-access (accessed 24.01.14).

They argue that the high yields are achieved at the expense of the environment due to the use of synthetic fertilizers, the exhaustion of water supplies, and the build-up of salt due to irrigation. They also argue that adoption of the new varieties leads to a monoculture more susceptible to new stresses such as diseases and insects, and decreases the level of biodiversity across the agricultural landscape. Borlaug countered that the Green Revolution allowed farmers to produce more grain on the same amount of land, and thus he viewed the high-yielding varieties as environmentally friendly. In 1930, one farmer fed 10 people; today one farmer feeds 155 people. The amount of income spent on food in the US was 25% in 1930 compared to 10% today. The world's grain production in 1950 was 692 million tons. By the 1990s, the world's farmers were producing 1.9 billion tons on approximately the same amount of land. If it were not for improved agricultural technology, 1.8 billion more hectares of land would have been needed. Future Green Revolutions must address these issues (IFPRI, 2003).

Other Issues

Increasing interest in eating meat in developing countries will place additional strains on the food production system. Obtaining our food needs from meat is highly inefficient because it takes so much more grain and water to produce meat. Approximately 35% of the world grain harvest is used to produce meat. The water required to produce rice is approximately $1600\,l\,kg^{-1}$ rice, whereas beef requires $12\,000\,l\,kg^{-1}$ beef. Although much of the world's peoples are vegetarian and healthy, several studies show that meat provides nutrients not available in plant sources. The increasing use of meat in diets, such as in China, will put more pressure on increasing the yield of maize, which recently surpassed rice in the amount produced, according to the U.S. Grains Council.

Water-use efficiency in crops is a trait under study by many researchers. All aspects of food production, and even biofuels, require much water. Seventy percent of the fresh water in the world is used by agriculture. The competition for water will intensify in the future as it becomes more of a scarce commodity. This issue is now receiving international attention.

Although the yield of maize has progressed well over the years with the advent of various new technologies such as hybrids and biotechnology (Figure 6), the yields of wheat and rice have plateaued. This is another cause for concern.

So, if the rate of increase in yields of maize via plant breeding and biotechnology is doing so well, why are people concerned? The concern stems from the lack of sufficient progress in the breeding of staples such as rice and wheat. For rice, the yield gains have decreased from 3.1% per year in the 1980s to only 0.8% in the 2000s. Similarly for wheat, the yield gains have decreased from 2.9% in the 1980s to only 0.4% in the 2000s (Figure 7). Approximately 50% of the yield gains generally are from improved genetics of the crop and approximately 50% from better management such as irrigation, fertilizers, pesticides, and planting protocols. The increase in food production via breeding offers good potential. In countries such as India, Pakistan, Nepal, and Bangladesh, approximately 80% of the area is rain-fed, which makes the maize quite vulnerable to abiotic stress such as drought. Extreme heat at flowering time can dramatically reduce yield. New technologies such as genetic engineering should help. For example, changing the photosynthetic system is a goal of several research programs. Maize is what is called a C4 species

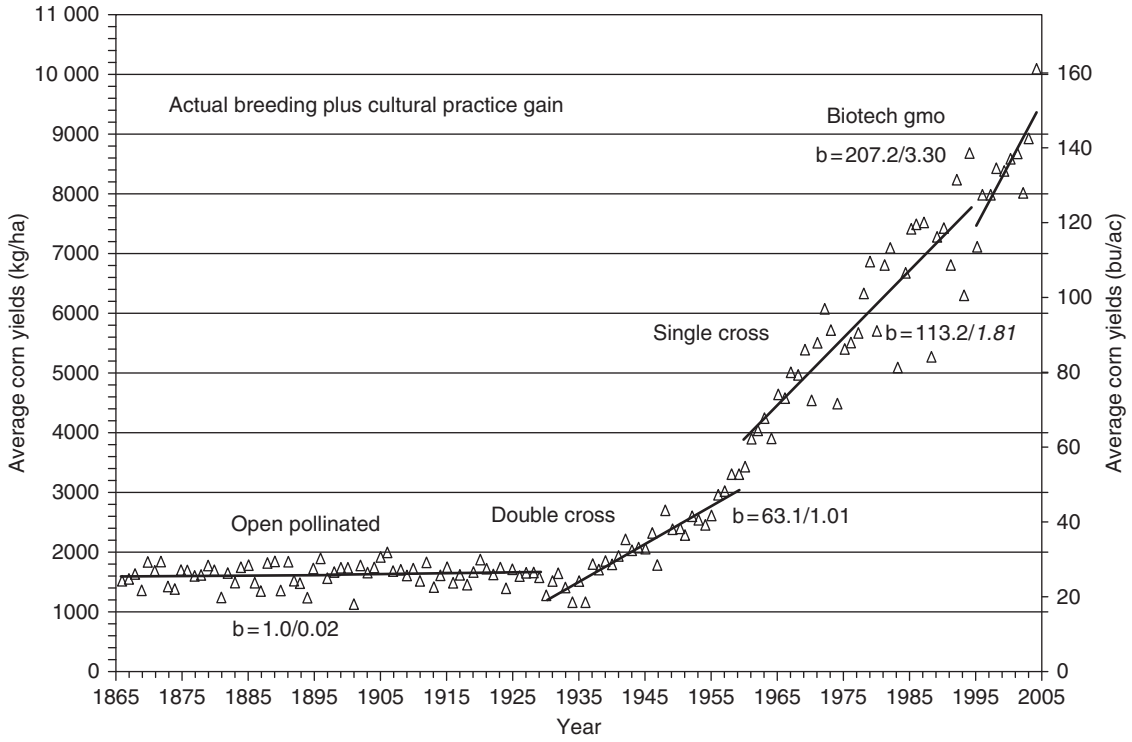

Figure 6 The maize yield-improvement graph from the time of open-pollinated varieties to the new biotech varieties.

that has benefits in situations such as drought, high temperatures, and nitrogen limitations. C4 plants such as maize also have an advantage over C3 plants such as rice and wheat in atmospheres with CO_2 limitations and high temperatures, theoretically giving C4 plants a mechanism to deal with climate change. C4 photosynthesis has evolved several times and, thus it seems reasonable that a C3 plant might be changed into a C4 plant via selection, mutagenesis, or genetic engineering.

Preservation of Biodiversity

The genetic resources existing around the world that will be used to create the next breakthrough in crop yields must be protected. In recent years, countries have begun to realize the value of the rich genetic materials that they possess. This has created considerable tension among countries and led to extensive examination of policies to govern the availability of such materials to others. This in turn has led to several treaties, protocols, and conservation methods to protect/share genetic resources. The International Rice Research Institute has a massive collection of rice accessions numbering over 100 000 types, all freely available to the public. CIMMYT has large collections of maize and wheat, also freely available. The Consultative Group on International Agricultural Research (CGIAR) and Bioversity International play a major role in germplasm collections, including the Fort Collins, Colorado, National Center for Genetic Resources Preservation. This is a long-term storage facility. "The mission of the National Center for Genetic Resources Preservation is to acquire, evaluate, preserve, and provide a national collection of genetic resources to secure the biological diversity that underpins a sustainable US agricultural economy through diligent stewardship, research, and communication." A recent development is the establishment of the Svalbard Global Seed Vault (affectionately known as the 'Doomsday Vault') in the frozen mountainside of Norway where a large cavern that is naturally cool contains much of the world's genetic variations of crops. In all, an estimated 1750 germplasm collections are said to exist with 7.4 million accessions.

Some believe that biodiversity was sacrificed when the Green Revolution was applied to new areas of marginal land. Others believe that genetic engineering will be a powerful tool in achieving biodiversity and meeting the huge demand for food by 2050. In 2012, biotech crops were grown on 170 million hectares by 17.3 million farmers. Developing countries now grow slightly over 50% of the total biotech crop. Genetically engineered cotton with insect resistance encompasses 80–90% of the crop. The top ten countries in growing biotech crops are the US, Brazil, Argentina, Canada, India, China, Paraguay, South Africa, Pakistan, and Uruguay (James, 2011).

Nutritional Changes in Food Supply

One tends to think that our food and feed crops are very good from a nutritional standpoint. However, the reality is that they can be improved, including through traditional breeding. For example, maize is deficient in the amino acids lysine and tryptophan, and beans are deficient in the amino acid

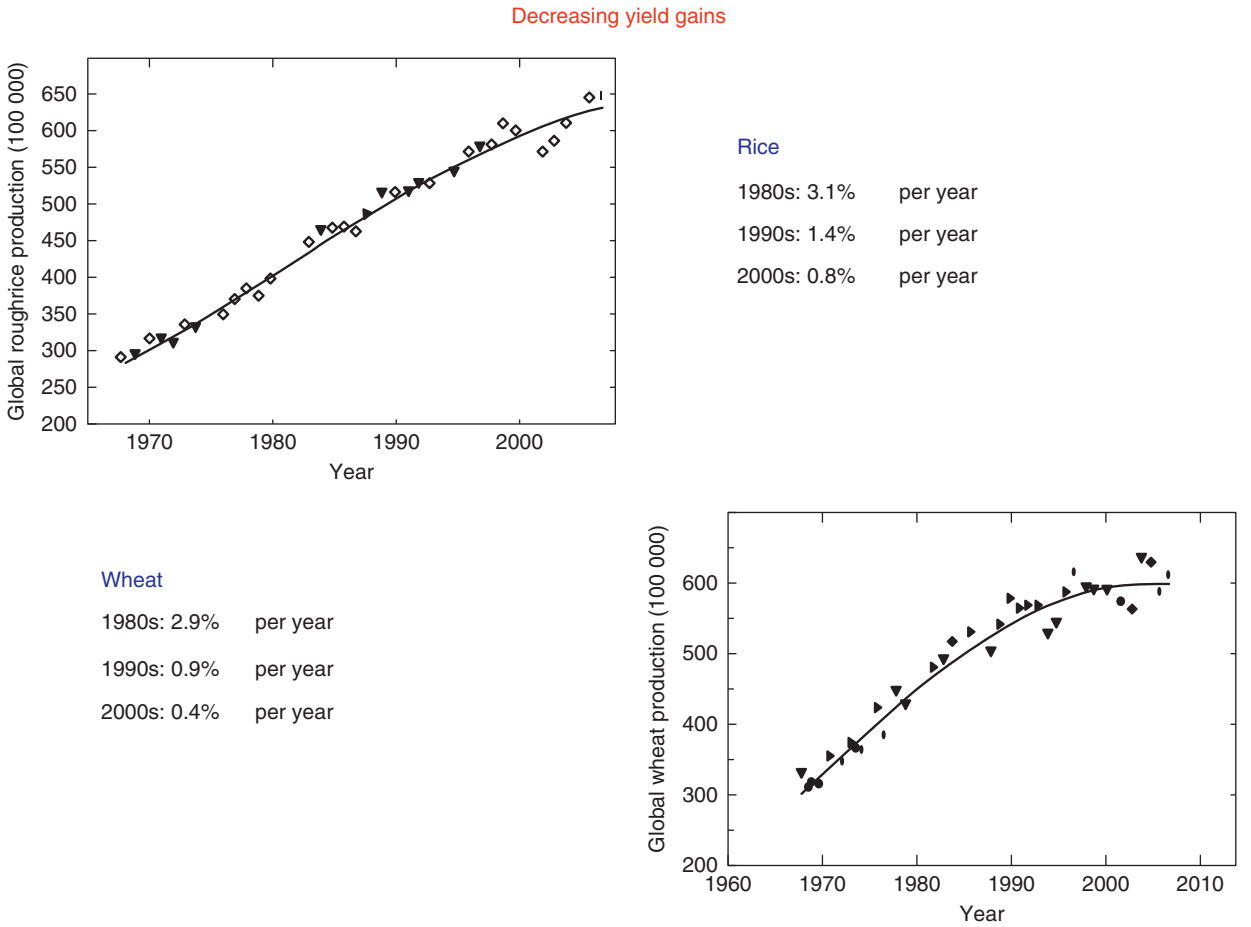

Figure 7 Yield curves for rice and wheat over three decades. Courtesy: Lewis Ziska, USDA.

methionine. A diet of maize and beans provides a relatively balanced diet. A type of maize called QPM or Quality Protein Maize has been developed mainly via a CIMMYT breeding program. Use of this variety of maize can alleviate a major protein deficiency in humans, called kwashiorkor. QPM maize is grown on approximately 9 million acres.

Micronutrients such as iron, zinc, iodine, and provitamin A are often deficient in crop plants. Varieties enriched in these micronutrients are being developed, especially under a program called Harvest Plus. Such varieties, bred to be adapted to various environmental and geographic regions, are under development. It is expected that rice enriched in provitamin A (or β-carotene), called Golden Rice, will be available soon. Our bodies need β-carotene in the diet in order to be converted to Vitamin A. Golden rice should solve a serious problem; approximately 500 000 children go blind every year due to Vitamin A deficiency. Many die because a deficiency in Vitamin A affects the immune system, making the individual more susceptible to diseases such as measles. There are considerable background data on the value of Vitamin A supplementation. Alfred Sommers of Johns Hopkins University provided 15 000 children with two doses of Vitamin A per year and found that it cut childhood morbidity and mortality by one-third. The World Bank and the Copenhagen Consensus indicate that supplementation with Vitamin A is one of the most effective health interventions in the world. Soon this could be achieved through genetically modified rice.

Role of Poverty

Poverty is often cited as one of the most important factors in malnutrition. Today 1.3 billion people live on less than US $1.00 per day, and 162 million people live on less than US $0.50 per day. This lack of money precludes many people, especially in the developing world from buying fruits and vegetables or even other grains that could provide a nutritionally balanced diet. The Green Revolution and current breeding and genetic engineering all can increase the income of farmers around the world. Many of these farmers are smallholder farmers and try to eke out an income from marginal lands. More income means that a more balanced diet can be available. It also means that both boys and girls can go to school and wear school uniforms not previously available to them because of the cost. Some of the recent agricultural programs are targeted toward the so-called 'Islands of Poverty' with the expectation that the funds will have an impact on hunger in these areas. Research indicates that rural poverty decreases by 1.83% for every 1% increase in agricultural growth.

Role of Women in Agriculture

Another targeted group is women – because women do much of the farming in the developing world while men are off to the cities to earn an income. Women are making more and more of the farming decisions. They grow a variety of crops and maintain some livestock and have to deal with many biotic (such as diseases) and abiotic stresses (such as drought), while also caring for children and other family members. These women are often malnourished or ill themselves. "Half of all farmers in the developing world are women. Many women work 6 h more a day than men on tasks like cooking, cleaning, and caring for children, which limits the time they have to farm. Women in the developing world are five times less likely than men to own land and their farms are usually smaller and less fertile."

The United Nations has set out several Millennium Development Goals to be achieved in the future, and these all have a direct bearing on the food security issue. The goals can be briefly stated as: (1) End poverty and hunger; (2) Achieve universal education; (3)Promote gender equality; (4) Reduce child mortality rates; (5) Improve maternal health; (6) Combat HIV/AIDS; (7) Ensure environmental sustainability; and (8) Develop a global partnership for development. All of these goals have direct implications relative to the Green Revolution and our attempt to reduce the 126 000 people dying every day due to malnutrition and poverty. Some of the targets of Goal #1, for example, are to "halve, between 1990 and 2015, the proportion of people whose income is less than $1 a day" and "halve, between 1990 and 2015, the proportion of people who suffer from hunger."

Paying Forward

Funding from the US has played a major role in maintaining a relatively plentiful supply of food. Some wonder whether the investment in international agriculture is cost effective for the developed world. Several hundred studies, according to Pardey *et al.* (2012) and Pardey and Alston (2011), show that the rates of return on American R&D investments are 40–60% per year with a benefit-cost ratio of at least 20:1. Investments in agricultural research take a long time to pay off – perhaps as long as 50 years. Even the development of a single new variety usually takes approximately 10 years. The International Food Policy Research Institute nicely sums up the "conditions under which the Green Revolution and similar yield-enhancing technologies are likely to have equitable benefits among farmers. These conditions include: (1) a scale-neutral technology package that can be profitably adopted on farms of all sizes; (2) an equitable distribution of land with secure ownership or tenancy rights; (3) efficient input, credit, and product markets so that farms of all sizes have access to modern farm inputs and information and are able to receive similar prices for their products; and (4) policies that do not discriminate against small farms and landless laborers (for instance, no subsidies on mechanization and no scale biases in agricultural research and extension). These conditions are not easy to meet. Typically, governments must make a concerted effort to ensure that small farmers have fair access to land, knowledge, and modern inputs."

Some argue that the Green Revolution of the 1960s was not the first green revolution. Sinclair and Sinclair (2010) suggest that the Sumarians developed what might be considered the basis of modern agriculture requiring math and written language along with markets. Water from the rivers (e.g., Euphrates) carried nitrogen to the crops and, over the years, nitrogen drove higher food production. This aspect of crop production was fostered via the ability to manufacture synthetic nitrogen by the Haber–Bosch process. Crop rotations were recognized as a good management tool, sometimes doubling yields. Therefore, one might consider that there were several green revolutions preceding the one in the 1960s and beyond. The wheat and rice Green Revolution is recognized as being unique, however, in that it allowed the saving of perhaps a billion people on the brink of starvation (Borlaug, 2009).

Support of Research and Development

Funding of agricultural research and development (R&D), both public and private, has decreased over the years. The success of the Green Revolution may have resulted in a complacent attitude among funding agencies. Given the recognition of the need for food and the cost of research and development, most people now view this reduction in funding as a huge mistake. Several agencies, NGOs, and private sector firms are now reversing this trend. Private funding plays an important role in taking the new developments to the farmer. However, many of the breakthroughs in research happen in the public sector. An investment in the public sector is essential to create the breakthroughs in helping the world meet the food demands of the future.

Biotechnology

Many believe that biotechnology, along with other technologies, will contribute significantly to food production in the future (Borlaug, 2007). Commercial biotech products started reaching the market in 1996, and this technology has been adopted more rapidly than any previous agricultural technology. New biotech crop varieties are being developed and tested that provide a more nutritious grain and meet certain industrial needs including biofuels. The so-called stacked varieties carry genes providing benefits in more than one aspect or make the product more durable in terms of disease or insect resistance. In some cases biotech products have saved an industry, such as papaya in Hawaii susceptible to the deadly papaya ring spot virus.

Biotechnology does not only encompass genetic engineering. Many efficient methodologies are emerging using DNA genetic markers that allow regions of the genome, if not the entire genome, to be followed in crosses. These markers also serve as a 'tag' for a particular trait that is often otherwise difficult to score. For example, submergence-tolerant rice is an exciting new development. Whereas normal rice dies after being submerged for 3 or 4 days, the gene 'submergence 1'

allows good yields even when the crop is submerged for 2 weeks or more. DNA regions around that gene can be followed in crosses, reducing the time to introduce the trait into new genetic backgrounds to 2.5 generations rather than 6 by traditional breeding. Now that the gene is cloned, the trait could be introduced by genetic engineering to prevent yield losses due to flooding.

Private companies often invest approximately $40 million to bring a new biotech variety to the market. This private sector investment has allowed new biotech products to come to the market. They also invest heavily in patents to recover the cost of development. Some people are concerned that the intellectual property protection provides too much corporate control. The USDA indicates that the company, the grower, and the consumer all benefit from products of biotechnology. Pollen flow creates situations where crosses may occur between the biotech variety and a wild but related species or nonbiotech varieties. However, there are ways to prevent these possibilities. A long-range concern deals with any environmental effects of biotech crops. Although many scenarios can be considered, no negative effects are clearly evident (National Academy of Sciences, 2002). The regulatory rules are taken very seriously; the rare breaking of a rule creates considerable concern, even if the effect is not a problem. These concerns and others have detracted from the use of biotech products in some countries, especially European countries.

The seventh annual PG Economics report on crop biotechnology impacts states that "Over the 15 year period covered in the report, crop biotechnology has consistently provided important economic and production gains, improved incomes and reduced risk for farmers around the world that have grown GM crops. The environment in user countries is benefiting from farmers using more benign herbicides or replacing insecticide use with insect resistant GM crops. The reduction in pesticide spraying and the switch to no-till cropping systems is also resulting in reduced greenhouse gas emissions. The majority of these benefits are found in developing countries" (Brooks and Barefoot, 2013).

M.S. Swaminathan (2011) has stated that "The bottom line for any biotechnology regulatory policy should be the safety of the environment, the well-being of farming families, the ecological and economic sustainability of farming systems, the health and nutrition security of consumers, safeguarding of home and external trade, and the biosecurity of our nation."

The Green Revolution of Today and the Future

The future of the Green Revolution revolves around technology that will increase food production but not at the expense of the environment. This concept is manifested in the term 'Evergreen Revolution' coined by M.S. Swaminathan, a compatriot of Borlaug, the first World Food Prize laureate (1986), and a major contributor to the Green Revolution in India. A reduction in the use of pesticides, judicious use of fertilizer, no-till (direct seed) planting, and efficient use of water are all part of having a productive and sustainable agriculture. In his speech at the 2011 World Food Prize event, Swaminathan stated that "During the next 25 years, the most important breakthrough we need is environmentally friendly and climate resilient farming techniques, which can increase productivity without adverse ecological side effects. This is what I have been referring to as the 'evergreen revolution.' We have to produce more food and agricultural commodities while per-capita arable land and irrigation-water availability diminish due to expanding biotic and abiotic stresses. To meet this challenge, we will have to harness all the tools of science, including recombinant DNA technology. By blending frontier technologies with traditional wisdom and ecological prudence, we can develop eco-technologies which can help us to achieve sustainable food security through the ever-green revolution pathway."

Sir Gordon Conway (1997) has called for a 'Doubly Green Revolution' where agriculture is highly productive, stable, resilient, equitable, and sustainable. He points out the value of the CGIAR (Consultative Group for International Agricultural Research), which was founded in 1971 and operates under the World Bank. There are now 15 CGIAR centers focusing on food crops, livestock, aquatic resources, water, forestry, and policy. More than 50% of the world's agricultural land planted with important food crops is derived from CGIAR research. Without these contributions, the world food production in developing countries would be approximately 8% lower. The CGIAR centers has also trained thousands of workers in the application of the information flowing from the research who return to their countries better prepared to enhance agricultural production. The centers also interact with the national research system and provide germplasm and information. This has been a powerful approach.

Heterosis in Plants

JA Birchler, University of Missouri, Columbia, MO, USA

© 2014 Elsevier Inc. All rights reserved.

Glossary

Additive It is the quantitative measure of traits or gene expression in a hybrid at the mid-parent value of the parents.
Complementation It is the combination of alleles in a hybrid that produce a normal phenotype from parental lines that are true breeding for a mutant phenotype.
Double-cross hybrid It is an early method of producing hybrid seed by crossing two inbred lines in order to generate hybrids and then using the two hybrids to produce abundant amounts of seeds. In tetraploids, this method is used for producing progressive heterosis.
Inbreeding It is the result of a crossing scheme by which an increasing number of genes become homozygous.
Inbreeding depression It is the reverse of heterosis, in which there is a decline in vigor with an increase of homozygous alleles with respect to the starting hybrid.
Nonadditive It is a quantitative measure of traits or gene expression in a hybrid that is not at the mid-parent value.
Polyploidy The multiple copies of the complete set of chromosomes beyond the diploid level.
Progressive heterosis In polyploids, the further increase in heterosis beyond the single-cross hybrid level that occurs in double-cross hybrids is defined as progressive heterosis.
Single-cross hybrid The progeny of a cross between two inbred lines.
Tetraploid An individual or line that contains four copies of the basic number of chromosomes of a species.

Heterosis is the phenomenon in which hybrids typically exhibit greater biomass, fertility, and other characteristics superior to the better of the two parents. The effects in the hybrids appear to involve a greater number of cells in individual plants (East, 1936), but there are also reports that cell size is altered in hybrids at least in some tissues (Greaves *et al.*, 2012). The developmental program is not perceptively changed but various aspects of the whole ensemble of traits do not necessarily correlate with each other (Flint-Garcia *et al.*, 2009), suggesting independent control. In hybrids between wide phylogenetic distances, hybrids can exhibit rather spectacular growth (Gravatt, 1914; Karpechenko, 1927).

The phenomenon of hybrid vigor has been used unwittingly in various civilizations in order to produce superior crops (Chen, 2010) but came under scientific investigation with the study of Darwin on inbreeding and outcrossing (Darwin, 1876). Darwin investigated various species that were self-pollinating or outcrossing and studied the consequences of inbreeding. He found an overall generalization that the species which typically were self-pollinating showed lesser effects of inbreeding than species that usually were outcrossing.

Genetic thought about heterosis began in the early 1900s following the rediscovery of Mendel's Laws (Bruce, 1910; Shull, 1908; Jones, 1917). In this case, inbred lines of maize were crossed together and the hybrids were found to exhibit excellent growth characteristics compared with both parents. This realization led to the development of inbred lines and eventually to the widespread use of hybrid maize following the suggestion by D. F. Jones of the double-cross hybrid method of producing seed for planting by farmers. Subsequent development of the use of cytoplasmic male sterility for the production of hybrid seed in various species (for review of early work: Duvick, 1959) expedited the production of hybrid materials. With the continual improvement of inbred lines, single-cross hybrids in maize are now used for hybrid seed production.

Potential Genetic Explanations

Despite the widespread use of hybrid vigor for commercial production in many plant species, the genetic and molecular basis of the phenomenon has been stubbornly resistant to an understanding. An early explanation was that different sets of slightly deleterious alleles were present in different inbred lines and when crossed together, the complementation of both sets from the two parents was responsible for hybrid vigor (Jones, 1917; Charlesworth and Willis, 2009). This undoubtedly occurs, but it is not yet clear whether the cumulative complementation across loci is the responsible mechanism. Another idea is that different alleles or genes interact in

the hybrid state to trigger the superior growth of the hybrid (Shull, 1908).

A variant of the complementation hypothesis was formulated from the finding in maize that different inbred lines have slightly different gene repertoires (Fu and Dooner, 2002). This presence–absence variation is manifested by the observation that genes present in one inbred are missing in others and vice versa. Hybrids would have a greater number of genes and would complement any detrimental effects of gene absence in the respective parents. The gene absences are more likely restricted to those that are nonvital or without effect on development. It is not known whether the classes of genes that can be deleted without major effects would nevertheless play a role in heterosis in hybrids between vigorous inbreds.

One set of observations that bear on this issue is that early in the study of heterosis it was realized that improvement of inbred lines did not diminish the observable level of heterosis (East, 1936). If the inbred lines were improved, it might be argued on the complementation model that the magnitude of heterosis would decline. But this is not observed (East, 1936). Duvick conducted a very thorough examination of this issue (Duvick, 1999). He used inbred lines developed at Pioneer Hi-Bred over decades and tested their yield when crossed to a common parent and of the inbred themselves. When yield was plotted by year, there was a progressive improvement in inbreds and hybrids. However, the contribution of heterosis to the yield was resistant to change and was of similar magnitude. In this extensive experiment, the purging of detrimental traits did not seem to impact heterosis.

How Many Genes Are Involved?

Typically, the phenomenon of heterosis appears to be affected by multiple genes. Inbreeding experiments have produced estimates in the order of dozens that are responsible (Sprague, 1983), but such estimates are fraught with many difficulties in their determination. In terms of the total gene repertoire (Schnable *et al.*, 2009) in maize, the number is quite small. Indeed, different combinations of inbred lines produce different levels of heterosis (e.g., see Flint-Garcia *et al.*, 2009) and sets of inbreds can be grouped together for 'combining ability,' which would be consistent with a small fraction of genes being involved. The recognition of individual genes involved with heterosis has been difficult perhaps because of the small contribution that each gene makes to the full spectrum of hybrid vigor.

In contrast, there have been numerous reports of single-gene heterosis. Convergence of mutant alleles of *erecta* and *angustifolia* in Arabidopsis and then examination of hybrids led to superior performance of the heterozygotes (Redei, 1962). Single genes in maize have been suggested to produce a heterotic effect (Dollinger, 1985). In tomato, this issue has been examined rigorously with single genes producing greater biomass for yield of the SINGLE FLOWER TRUSS locus (Krieger *et al.*, 2010). Also in tomato, the transfer of small genomic regions from wild tomato into the domesticated variety and then testing for heterosis in heterozygotes revealed that small portions of the genome were effective, leading to the suggestion that single-gene allelic differences were responsible (Semel *et al.*, 2006).

It should be noted that the multigenic view and the single-gene effects are not mutually exclusive. The single-gene effects might operate in such a manner that the allelic differences are sufficiently great that their impact can be found in experimental comparisons. In other circumstances, it might be the case that the allelic differences are more subtle and therefore the contribution of each gene to the total effect is much less.

Gene Expression in Hybrids and Inbreds

Numerous studies have examined gene expression in inbreds and hybrids. A variety of findings have emerged from these studies (Andorf *et al.*, 2010; Chen *et al.*, 2008, 2010; Frisch *et al.*, 2010; Groszmann *et al.*, 2011; He *et al.*, 2010; Paschold *et al.*, 2010; Hoecker *et al.*, 2008; Huang *et al.*, 2006; Meyer *et al.*, 2007; Ni *et al.*, 2009; Pea *et al.*, 2008; Shen *et al.*, 2012; Stupar *et al.*, 2008; Stupar and Springer, 2006; Sun *et al.*, 2004; Swanson-Wagner *et al.*, 2006; Thieman *et al.*, 2010; Uzarowska *et al.*, 2007; Wang *et al.*, 2006; Wei *et al.*, 2009; Zhang *et al.*, 2008; Zhuang and Adams, 2007). Many genes are additive in the hybrids being at the mid-parent value. Others deviate toward the value of one parent or the other and some expressions lie outside the parental values. The proportion of genes that exhibit these various behaviors is variable among experiments and may differ depending on the experimental methods, tissues, species, or developmental stage examined. There are reports that the numbers of genes that exhibit non-additive (deviating from the mid-parent value) expression are greater in more heterotic hybrids of various species (Li *et al.*, 2009, 2011; Riddle *et al.*, 2010). The basis of this observation is unknown and might reflect different mixtures of cell types in hybrids or true changes in gene expression associated with differing magnitudes of heterosis. Others suggested that potential mechanisms involve metabolic networks (Fievet *et al.*, 2010; Lisec *et al.*, 2011), protein quality control (Goff, 2011), control of cell number (Guo *et al.*, 2010), and altered circadian rhythms (Ni *et al.*, 2009).

Heterosis in Polyploids

The behavior of heterosis in polyploids has been discussed much less than the behavior in presumed diploids and has sometimes been dismissed in discussions of mechanism. However, given that all plants have a history of repeated polyploidization and then evolutionary return to a more diploid state (Jiao *et al.*, 2011), it would seem that these considerations are important. Indeed, heterosis is more likely to have played a role in this cycle of polyploidization and diploidization.

The first issue of note involving heterosis in polyploids is that there is evidence of a genomic dosage effect on the magnitude. This realization was first made by East (1936), involving tobacco polyploids in which different doses of the distinct genomes contributing to the polyploid were present. Although the results from these experiments were straightforward, they did involve genomes that originated from

different species. It is unknown how this parameter might affect the results and thus how this information might be incorporated into developing hypotheses about heterosis.

To examine this question within a single species, Yao *et al.* (2013) produced triploid maize that were derivatives of two different inbred lines and also two types of triploid hybrids (ABB and BAA). The matched diploids were also studied. The reciprocal hybrids at the diploid level were very similar to each other as is usually the case. However, at the triploid level, the two types of triploid hybrids exhibited heterotic effects that were quite distinct from each other using better parent heterosis. However, when a weighted average was produced and mid-parent heterosis was examined, the two types of triploid hybrids produced a very similar result. These two types of analysis indicate that genomic dosage plays a role in heterosis and the effects are proportional to the change in dosage, i.e., the weighted averages become basically equivalent. These results suggest that heterosis is affected by dosage-sensitive genetic factors similarly to many quantitative traits (Tanksley, 1993; Liu *et al.*, 2003; Lee *et al.*, 1996). They also indicate that complementation of detrimental recessive alleles from the different parents is unlikely to be the sole contributor to heterosis.

Progressive Heterosis

Another aspect of heterosis of note is the phenomenon of progressive heterosis (Bingham *et al.*, 1994; Groose *et al.*, 1989). This phenomenon was first defined in alfalfa, an autotetraploid. The finding was that single-cross hybrids between inbred lines would produce a certain level of hybrid vigor, but when two single-cross hybrids were mated, the progeny with now more potential alleles present at each locus exhibited even greater heterosis. In other words, by maximizing the allelic diversity, there was an increase in the magnitude of heterosis. Although this phenomenon has been most thoroughly studied in alfalfa, related results have been found in maize and potato (Levings *et al.*, 1967; Mok and Peloquin, 1975; Randolph, 1942; Sockness and Dudley, 1989a,b; Chase, 1980; Riddle and Birchler, 2008). It is also likely that the fact that heterosis can be observed in hexaploid wheat (Briggle, 1963) and octoploid triticale (Goral *et al.*, 2005), when different varieties are crossed together, reflects a similar phenomenon.

The genetic basis of progressive heterosis has not been explored in depth. The hypothesis that heterosis results from complementation would require that any four inbred lines would have different slightly deleterious mutations so that in the single-cross hybrids some of them would be complemented in any combination of inbreds. However, it would also require that for the double-cross hybrid, there must be still different sets of recessives that are homozygous in the two single-cross hybrids so that they would be complemented in the double cross to provide a further boost via complementation. But at the same time, the double-cross hybrid could not return any loci to the homozygous state to the point of canceling the added gain from complementation because complementation would be eliminated for these loci. The genetic parameter that correlates with progressive heterosis is the maximization of allelic diversity. There is no theoretical or experimental exploration of the basis of this relationship.

Inbreeding Depression

A third aspect of heterosis in polyploids of note is that inbreeding curves between matched diploids and tetraploids are much more similar than predicted by the mechanisms of homozygosis at the two ploidy levels (Alexander and Sonnemaker, 1961; Busbice and Wilsie, 1966; Rice and Dudley, 1974). For example, at the diploid level, a heterozygote (A/B) when selfed will produce half of the next generation as homozygous and the other half as heterozygous for that locus. At each subsequent generation, the amount of heterozygosity will decline by one half. In contrast, for a heterozygous tetraploid (A/A/B/B), the homozygosis will depend on the location of a gene on the chromosome, but for genes near the centromere, a self-pollination will produce one in 36 homozygotes for the two respective alleles for a total of one in eighteen homozygous progeny. There is, however, one half of the progeny that remains heterozygous (A/A/B/B). The other classes of progeny have different numbers of alleles present (A/B/B/B or A/A/A/B). Certainly, these conditions described above apply to individual loci without regard to how interactions occur across the genome, which would no doubt complicate how inbreeding operates in practice.

Another consideration that might slow the inbreeding in a tetraploid is that pollen from a tetraploid can be heterozygous and potentially exhibit a heterotic effect on growth. This situation might favor fertilization by heterozygous pollen grains that can outcompete any homozygous pollen. In diploids, all pollen grains are haploid and heterozygosity will not occur. There has been no concerted study of how this fact of polyploidy biology might affect inbreeding, but it would be expected to slow inbreeding rather than accelerate it.

The above considerations suggest that the homozygosis of recessive mutations would proceed at a vastly different rate in matched diploids and tetraploids. However, when matched diploid and tetraploid hybrids are produced and then carried through a regime of continued self-pollination over generations, the decline in vigor between the two ploidy levels is similar. This finding was first thoroughly characterized in alfalfa (Busbice and Wilsie, 1966), but related findings have been made in maize (Rice and Dudley, 1974). These data would suggest that the decline in vigor is at least not solely due to the homozygosis of recessive alleles. Busbice and Wilsie (1966) suggested that a shift in the allelic numbers might contribute to a similar inbreeding curve. This interpretation is consistent with the genomic dosage effects impacting heterosis noted above. The shift in allelic numbers in a tetraploid might not produce an exactly equal inbreeding curve to the diploid, but it is unlikely that any experiment has been sufficiently large to distinguish what is certain to be a subtle difference.

Conclusion

Given the central role that heterosis plays in crop production, continued investigation of the genetic and molecular basis of heterosis is clearly justified. As further data become available, the possible explanations and models to explain hybrid vigor will become constrained as the scientific community

asymptotically approaches a consensus. An elucidation of the underlying basis of heterosis might provide the ability to manipulate and maximize it for crop production.

Human Nutrition: Malnutrition and Diet

JL Slavin, University of Minnesota, Saint Paul, MN, USA

© 2014 Elsevier Inc. All rights reserved.

Glossary

Food security Availability and access to food.
Indispensible amino acids Amino acids whose carbon skeletons cannot be synthesized from simpler molecules in animals, and therefore must be provided in the diet.
Macronutrients Fats, carbohydrates, and proteins; components of the diet that provide calories.
Micronutrients Vitamins and minerals, compounds needed in the diet in small amounts to aid metabolism. Micronutrients do not provide calories, but are involved in metabolic pathways.
Protein quality Ability to provide the nitrogen and amino acid requirements for growth, maintenance, and repair.
Recommended Dietary Allowances (RDA) The amount of essential nutrients needed to provide nutrients needs of most individuals in the population.

Principles of Human Nutrition

Humans are mammals and start life by drinking their mother's milk. Breast milk of humans is high in fat (50% of calories) and carbohydrate and low in protein. Human breast milk composition is considered closest to marsupials, species that carry their young around to allow for regular infant feeding. Best practices for infant feeding supports that mothers have easy access to their infants as young babies will feed up to 12 times per day.

Calories and protein needs are highest per pound body weight for infants and children. Babies triple their body weight in the first year, which requires regular feeding of breast milk or high-quality infant formula. Failure to thrive in infants is linked to infrequent feeding or dilution of infant formula to lower costs. Nutrient content of breast milk is maintained in women on inadequate diets, although milk volume may decrease. Often in a famine, the breastfed infant or toddler is the best nourished in the population.

When resources are scarce, nutritional priority should go to pregnant and lactating women, infants, and children. During growth and development, calorie and protein needs are high and nutrient insults are much more serious than for adults.

Generally, the diet expands during the weaning stage. Usual recommendations are to include foods high in iron as breast milk is particularly low in iron. Interestingly, the bioavailability of iron in breast milk is very high so breastfed babies tend not be iron deficient. Mainstays of the local diet are then introduced to the child. In most cultures, these are high-starch foods, such as rice, cassava, potatoes, corn meal, or bread. Fruits and vegetables are also introduced into the diet and provide the needed vitamins and minerals. As breast milk consumption decreases, good-quality protein sources also are needed in the diet. Animal proteins, such as cow's milk, meat, fish, and eggs are highest in protein quality. Other protein sources include legumes, nuts, and grains.

Macronutrients

Unlike vitamins and minerals, fats, carbohydrates, and proteins, the macronutrients, can substitute for each other to meet the body's energy demands (Otten *et al.*, 2006). In diet planning, protein is considered first as it is the most important macronutrient. On average, approximately 15% of the total calories in the diet should come from protein.

Protein is the major structural component of all cells in the body and functions as enzymes, hormones, and other important molecules. Proteins are also important as a source of calories and low-calorie diets are necessarily high in protein. The Recommended Dietary Allowance (RDA) for both men and women is 0.80 g of good quality protein per kg body weight per day and is based on careful analyses of available nitrogen balance studies. Data were insufficient to set a tolerable upper intake level for protein or amino acids.

The Acceptable Macronutrient Distribution Range (AMDR) for protein is 5–20% of total calories for children 1–3 years of age, 10–30% of total calories for children 4–18 years of age, and 10–35% of total calories for adults older than 18 years of age (Otten *et al.*, 2006).

Both protein and nonprotein energy (from carbohydrates and fats) must be available to prevent protein-energy malnutrition (PEM). If amino acids are not present in the right balance, the body's ability to use protein will be affected. Protein deficiency affects all organs and is particularly concerning during growth and development. The risk of adverse effects from excess protein intake from food appears very low. The data are conflicting on the potential for high-protein diets to produce gastrointestinal effects, change nitrogen balance, alter mineral absorption, or affect chronic diseases such as osteoporosis or renal stones.

Carbohydrates

Carbohydrates – the sugars, starches, and fibers found in fruits, vegetables, grains, and milk products – are an important part of a healthy diet. Sugars and starches supply energy to the body in the form of glucose, which is the primary energy source for the brain, central nervous system, and red blood cells. Fibers, unlike sugars and starches, do not supply glucose to the body. They promote healthy laxation and decrease the

 doi:10.1016/B978-0-444-52512-3.00066-8

risk of certain chronic diseases such as coronary heart disease (CHD), obesity, and colon cancer (Slavin, 2008).

The nomenclature for carbohydrates is somewhat confusing. Sugars can be one sugar unit (monosaccharides) such as glucose, fructose, and galactose; and they can be two sugar units linked together (disaccharides) such as sucrose, lactose, and maltose. A further distinction is sometimes made between intrinsic and extrinsic sugars. The term intrinsic sugar means those sugars that are naturally occurring within a food, whereas extrinsic sugars are those that are added to foods. The US Department of Agriculture (USDA) has defined added sugars as sugars and syrups that are added to foods during processing or preparation, and also includes sugars and syrups added at the table. There is no difference in the molecular structure of sugar molecules, whether they are naturally occurring in the food or added to the food (Hess *et al.*, 2012).

Starches are many glucose units linked together (polysaccharide). Although most starch can be broken down by human enzymes into glucose for absorption, some starch does not undergo digestion in the small intestine and is called resistant starch, which is found in plant foods such as legumes, pasta, and refrigerated cooked potatoes. Fibers, like starches, are polysaccharides made up mostly of glucose units (in the case of cellulose) or other combinations of monosaccharides. However, the monosaccharides in fibers are bonded to each other differently than they are in starches, and human enzymes cannot break the bonds in the fibers. Thus, fibers are not absorbed from the small intestine and pass relatively intact into the large intestine, as does resistant starch.

Recommendations for the Intake of Sugars and Starches

The Institute of Medicine (IOM) report Dietary Reference Intakes for Energy, Carbohydrate, Fiber, Fat, Fatty Acids, Cholesterol, Protein, and Amino Acids (IOM, 2005) established an RDA for carbohydrate of 130 g day^{-1} for adults and children. This value is based on the amount of carbohydrate (sugars and starches) required to provide the brain with an adequate supply of glucose. Glucose is the only energy source for red blood cells and the preferred energy source for the brain, central nervous system, placenta, and fetus. When muscle cells operate anaerobically (without oxygen), they rely 100% on glucose. If glucose is not provided in the diet and the body's storage form of glucose (glycogen) is depleted, the body will break down protein in the muscles to maintain glucose blood levels and supply glucose to the brain (IOM, 2005).

The IOM also set an AMDR for carbohydrate of 45–65% of total calories. At the low end of this range it is very difficult to meet the recommendations for fiber intake, and at the high end of the range overconsumption of carbohydrates may result in high blood triglyceride values. A comparison of the RDA to the AMDR shows that the recommended range of carbohydrate intake is higher than the RDA. For example, if an individual with a caloric intake of 2000 kcal day^{-1} were to consume 55% of calories as carbohydrate (the mid-range of the AMDR) that would mean that 1100 kcal would be from carbohydrate. This equates to 275 g carbohydrate (1 g carbohydrate = 4 kcal), well above the RDA of 130 g day^{-1}. In summary, the primary beneficial physiological effect of sugars and starches, and the basis for setting an RDA for carbohydrate, is the contribution of glucose as an energy source for the brain. However, the amount of glucose needed by the brain is lower than the AMDR for carbohydrate (45–65% of total calories).

Recommendations for the Intake of Fiber

Fibers are different from sugars and starches in that they are not digested and absorbed in the small intestine and converted to glucose. Humans do not have the necessary enzymes to break down fibers into their constituent parts so that they can be absorbed into the body. Therefore, fibers pass from the small intestine into the large intestine relatively intact. There they can be fermented by the colonic microflora to gases such as hydrogen and carbon dioxide and to short-chain fatty acids. Although fibers are not converted to glucose as are sugars and starches, some of these short-chain fatty acids are absorbed and can be used for energy in the body. However, determining the amount of calories supplied by fiber is complex because it depends on such factors as the fermentability of the fiber, the individual's colonic microflora, how long fiber stays in the colon, etc. The IOM has set an Adequate Intake (AI) value for fiber of 14 g of fiber per 1000 kcal. This AI is based on the totality of the evidence for fiber decreasing the risk of chronic disease and other health-related conditions, but the actual numbers for the AI were derived from the data supporting a decreased risk for the development of CHD. The major food sources of fiber are fruits, vegetables (particularly legumes), and grains. Milk does not contain fiber although certain milk-containing products may.

Major Food Sources of Carbohydrates (Fruits, Vegetables, Grains, and Milk Products)

Because the RDA for carbohydrate is relatively easy to meet, and carbohydrates (sugars and starches) supply calories, it is important to choose food sources of carbohydrates carefully to maximize nutrient value per calorie. Also, because fiber has known health benefits (e.g., promoting a healthy laxation and decreasing the risk of CHD and obesity) it is advisable to select high-fiber foods where possible. For example, fruits provide sugars, usually at a relatively low calorie cost, and they are important sources of fiber and at least eight additional nutrients. Some vegetables are high in starch and some are very low in both starch and sugar, but they all are important sources of fiber. They also are important source of nutrients, including vitamins A, E, and folate and potassium, and, in general, do not supply many calories. Whole grains are high in fiber and starch, but most of the fiber is removed when grains are refined. Milk and milk products contain the sugar lactose and generally do not contain fiber.

Fat

Fats in food provide a major source of energy for the body. Humans store energy as fat.

During malnutrition, the body will burn fat for energy. But metabolically it takes carbohydrate to burn fat. This is often referred to as 'fat burns in the flame of carbohydrate.' In starvation, there are no carbohydrate stores left in the body. The body cannot burn fat for energy without carbohydrate so the body starts breaking down body protein to make carbohydrate. As starvation continues, the body adapts to other pathways to burn fat which yield ketone bodies.

Dietary fat is either saturated or unsaturated. Total fat intake is generally 20–35% of energy for adults; higher levels are recommended for growing children. The main fat sources are butter, margarine, vegetable oils, whole milk, meat, and baked products. Breast milk supplies 50% of calories as fat. Thus, usual feeding practices for children are to maintain higher intakes of fat for children. Usual recommendations are to transition to whole cow's milk from breast milk during the weaning process, generally after age 1 year.

Two unsaturated fatty acids, linoleic and α-linolenic are essential and thus must be obtained from foods. Only small amounts of these essential fatty acids are needed, therefore, inadequate intakes are not practical nutritional problems.

Proteins

Different sources of protein vary widely in their chemical composition as well as in their nutritional value. The quality of a protein is an expression of its ability to provide the nitrogen and amino acid requirements for growth, maintenance, and repair. Protein quality is determined by two factors, digestibility and amino acid profile.

Whole wheat flour is low in lysine and navy beans are low in methionine. Thus, the concept of complementing proteins is to encourage consumption of vegetarian foods low in one amino acid with vegetarian foods low in another – examples being beans and rice, a peanut butter sandwich, or hummus on crackers.

Recommendations for the Intake of Amino Acids

Dispensable, indispensable, and conditionally indispensable amino acids are needed in the human diet. The nine indispensable amino acids are those whose carbon skeletons cannot be synthesized from simpler molecules in animals, and therefore must be provided in the diet. The indispensable amino acids are histidine, isoleucine, leucine, lysine, methionine, phenylalanine, threonine, tryptophan, and valine. Dispensable amino acids are alanine, aspartic acid, asparagine, glutamic acid, and serine. Conditionally, indispensable amino acids include arginine, cysteine, glutamine, glycine, proline, and tyrosine.

Major Food Sources of Proteins

Proteins found in animal sources such as meat, poultry, fish, eggs, and milk provide all nine indispensable amino acids and are referred to as 'complete proteins.' Proteins found in plants, legumes, grains, nuts, seeds, and vegetables tend to be deficient in one or more of the indispensable amino acids and are called 'incomplete proteins.' Isolated proteins from dairy products (casein/whey), soy, and other products can also be added to foods or taken as dietary supplements. Isolated amino acids are also sold as dietary supplements, but intakes tend to be low. Data are limited on the adverse effects of high amounts of amino acids from dietary supplements and therefore caution is recommended in consuming any single amino acid at levels significantly above those found naturally in foods.

For men and women, protein provides approximately 15% of total calories. As calorie intake decreases, it is essential to increase the percentage of calories from protein to consume the RDA for protein. Thus, the wide range of 10–35% of total calories coming from protein for adults is based on the large range of calories consumed depending on physical activity and body size.

Any animal protein, such as eggs, meat, fish, and milk are high-quality proteins and are 'complete,' meaning they supply all the nine essential amino acids needed to build body protein (Otten *et al.*, 2006). Plant proteins, from grains, legumes, nuts, seeds, and vegetables are 'incomplete' as they do not have adequate amounts of all essential amino acids. Generally, grains are low in the amino acid lysine, whereas legumes are low in the amino acid methionine. Because foods are eaten in combination, it is not difficult to build complete proteins. Many traditional eating patterns, such as beans and rice, beans and corn tortillas, or a peanut butter sandwich combine legumes and grains and provide complete protein.

Both protein and nonprotein energy (from carbohydrates and fats) must be available to prevent PEM. If amino acids are not present in the right balance, the body's ability to use protein will be affected. Protein deficiency affects all organs in the body.

Protein quality of a food depends on the amino acid composition and digestibility of the protein. If the content of a single indispensible amino acid in the diet is less than the individual's requirement, then this deficiency will limit utilization of other amino acids and prevent normal rates of protein synthesis. There is no perfect way to measure protein quality; however chemical score and protein efficiency ratio (PER) are both used to rank protein quality.

Chemical score is determined in comparison to egg protein, which is considered the reference protein and given a score of 100. The amino acid patterns in all protein sources are measured and the amino acid in the test protein with the lowest level is called the limiting amino acid of the protein. The value of the percentage is the chemical score (**Table 1**). In this system, fish has a chemical score of 71, whereas lentils have a chemical score of 31.

PER requires monitoring the growth of laboratory animals. PER is defined by dividing the weight gained by the animal by the weight of protein consumed. The conditions for gathering PER data are standardized. With this system, animal products are the highest quality proteins, whereas plant products are not complete and are of lower quality (**Table 1**).

Dietary reference intakes for total protein vary by life stage group. Values are based on grams of protein needed per kilogram of body weight. Values are highest in infancy (1.52), decrease during childhood from 1.2 to 0.85, and then remain at 0.8 after age 19. Values increase during pregnancy (1.1) and lactation (1.3).

Table 1 Measures of protein quality (Source: National Research Council, 1974)

Protein	*Chemical score*	*Protein efficiency ratio*
Egg	100	3.92
Fish	71	3.55
Beef	69	2.30
Sunflower seed	61	2.10
Casein	58	2.86
Oats	57	2.19
Rice	56	2.18
Peanuts	55	1.65
Soybeans	47	2.32
Wheat	43	1.53
Lima beans	41	1.53
Maize (corn)	41	1.12
Lentils	31	0.93

Both protein and nonprotein energy must be available to prevent PEM. Worldwide PEM is common in both children and adults and is associated with deaths of approximately 6 million children each year (FAO, 2010). In developed countries, PEM is seen mostly in hospitals in patients with chronic disease and in the elderly. Protein deficiency affects all parts of the body, especially the immune system, so malnourished people are more susceptible to all diseases and infections. Gut mucosal systems and permeability are particularly affected, so refeeding programs are often unsuccessful because the body can no longer digest and absorb foodstuffs.

The AMDR for protein in adults is 10–35% of total calories. Because protein requirements are set with body weight, low-calorie diets must contain a higher percentage of protein to supply the RDA for protein.

After protein needs are met, diets must also supply the remaining essential nutrients, fats, carbohydrates, fiber, vitamins, minerals, and fluids. When adequate amounts of a variety of foods are consumed, it is generally not difficult to obtain the essential nutrients. Some exceptions include iron and zinc, which may be low in plant sources and the iron and zinc that is in the foods is not bioavailable. Additionally, calcium may be a problem nutrient, especially during growth and development. Thus if children do not have access to dairy products, other sources of calcium will need to be consumed. Soups made with meat or fish with bones may be the source of the necessary calcium. Some dark green vegetables and seeds also provide calcium to the diet.

Micronutrients

Vitamins

There are 13 essential vitamins, 4 fat soluble and 9 water soluble. Fat-soluble vitamins include vitamins A, D, K, and E. Because of the importance of these vitamins to health and past low intakes, vitamin A and D are added to milk in the US to ensure that children get adequate intakes. Past feeding programs have given cod liver oil to children to make sure they have adequate levels of vitamin D to prevent rickets, the deficiency disease associated with low intakes of vitamin D.

Vitamin A deficiency causes xerophthalmia, which is estimated to affect 3–10 million children (mostly in developing countries) annually. Of those affected 250 000–300 000 go blind every year. Xerophthalmia is an irreversible drying of the conjunctiva and cornea. Efforts to deliver vitamin A to susceptible populations are difficult as preformed vitamin A occurs mostly in animal products. Golden rice, a genetically modified rice with high levels of vitamin A shows great promise, but to date has had limited acceptance (Chassy, 2010).

Vitamin K is involved in blood coagulation and infants in the US and Canada receive routine injections at birth to prevent bleeding diseases. Vitamin K deficiencies are rare and limited to individuals with malabsorption syndromes. Vitamin E functions as an antioxidant in the body. Deficiency is rare except with fat malabsorption syndromes or PEM.

The water-soluble vitamins include vitamin C, thiamin, riboflavin, niacin, vitamin B_6, vitamin B_{12}, pantothenic acid, biotin, and folic acid. Fruits and vegetables are typically concentrated in water-soluble fibers, especially vitamin C and folic acid. B_{12} is found only in animal products, whereas vitamin B_6 is also associated with foods high in protein. Niacin can be made from the amino acid tryptophan, hence diets deficient in protein and niacin are associated with pellagra, the deficiency disease of niacin.

Minerals

There are 20 minerals that are essential to the humans. Calcium and iron are most likely to be deficient in humans. Calcium plays a role in bone health and is most important during childhood. Foods rich in calcium include milk, yogurt, cheese, kale, and broccoli. Calcium may be poorly absorbed from foods that are rich in oxalic acid or phytic acid, such as kale. Calcium intake may drop significantly during weaning if no dairy products are available to the weaned child.

Iron-deficiency anemia is the most common nutritional deficiency in the world. Functional indicators of iron deficiency include reduced physical work capacity, impaired cognitive function, and adverse effects for both the mother and the fetus (premature delivery, low birth weight, and increased perinatal infant mortality). Approximately half of the iron from meat, poultry, and fish is heme iron, which is highly bioavailable. The rest is nonheme iron which is less readily absorbed in the digestive tract. All vegetable foods, grains, vegetables, legumes contain nonheme iron.

Water

A safe, abundant water source is also essential to good health. The body is well adapted to balance water needs if electrolytes such as sodium and potassium are also available in the food supply, typically in fruits and vegetables. Fluid problems generally develop because of contaminated water supply or diarrhea; these problems are usually most serious in infants, children, and the elderly.

Growth and Development – When Are Nutrient Needs Highest?

Energy is required to sustain the body's various functions including respiration, circulation, metabolism, physical work, and protein synthesis. Nutrient needs are highest for infants and young children, although these needs are on a body weight basis. Calorie needs are also greatest during growth and development, so increased daily calorie needs during pregnancy average 300 kcal day^{-1}, whereas increased daily calorie needs during lactation average 500 kcal. Children and adolescents need higher calories during growth spurts. Energy needs are also based on lean muscle weight, so adolescent males in a growth spurt generally need the highest amount of calories in a family.

Calorie needs are also affected by energy expenditure. Hard physical labor will require many more calories than the calories needed for basal metabolism. Inactivity, the usual state in most developed countries, is generally linked to obesity because food is readily available, yet so few calories need to be expended during the usual day's activities.

Malnutrition Is Most Likely in Children and the Elderly

Food security refers to the availability of and access to food. Other issues in food security include access, utilization, stability, and the contribution of vulnerability of individuals (Pinstrup-Andersen, 2009). According to the Food and Agriculture Organization of the United Nations (FAO) food security exists when all people, at all times, have physical, social, and economic access to sufficient, safe, and nutritious food that meets their dietary needs and food preferences for an active and healthy life. The 2010 FAO report 'The State of Food Insecurity in the World' estimated that globally 925 million people are undernourished. The FAO defined undernourishment as when caloric intake is below the minimum dietary energy requirement (Broca, 2002).

One of the challenges in discussing food insecurity is the lack of a standardized measure which works in all settings and cultures. Barrett (2010) suggests that the difficulty in measurement is because food insecurity is a multidimensional concept that encompasses aspects of availability, access, and utilization. Studies quoted in the literature use a variety of tools including the USDA Household Food Security Scale, the Radimer/Cornell Hunger and Food Insecurity Instrument, and the Household Food Insecurity Access Scale (Ivers and Cullen, 2011).

Food security requires nutritional adequacy. Any individual that has micronutrient deficiency is food insecure. In a US study, food insecurity was associated with reduced micronutrient intake among women of childbearing age (Rose and Oliveira, 1997). Problem nutrients included calcium, iron, vitamin E, magnesium, and zinc. Nutrient deficiencies can be made worse by other medical conditions. Human immunodeficiency virus infections increase resting metabolic expenditure and impair absorption and utilization of nutrients (Katona and Katona-Apte, 2008).

Severe acute malnutrition (SAM) is a consequence of sudden food shortage and is associated with loss of a person's body fat and wasting of their skeletal muscle (Picot *et al.*, 2012). Many of the affected are already undernourished and susceptible to disease. Infants and young children are most susceptible as their nutrient needs are highest and they depend on others to provide food and nourishment. SAM is associated with high levels of morbidity and mortality.

Picot *et al.* (2012) evaluated the effectiveness of interventions to treat infants and children aged <5 years who have SAM. A total of 8954 records were screened and 74 articles (describing 68 studies) met the inclusion criteria and were included. Generally, evidence was lacking or inconclusive. No dietary treatment was found to offer significant benefits, although individual studies assessed zinc and potassium. Additionally, no dietary treatment for the diarrhea seen with acute malnutrition showed any significant difference on recovery.

No doubt the best strategy is to prevent malnutrition, as dietary treatment is difficult and often not successful.

Overfed, but Undernourished – the New Malnutrition

In many developed countries, the new malnutrition is obese children who are food insecure. Often in these situations, children have access to poor quality foods that are too low in protein and micronutrients to promote adequate growth and development. In the US, 21% of children live in a food-insecure household (Nord *et al.*, 2007), which means that children in the household live without the financial means to access enough food for active, healthy living.

Eisenmann *et al.* (2011) reviewed studies on the relationship between obesity and food insecurity. Although it is generally accepted there is a relationship, the majority of studies studies with larger sample sizes found no relationship between body weight and food insecurity. Smaller studies in rural Malaysia found that 58% of food-insecure women were overweight compared with 38% of those who were food secure (Shariff and Khor, 2005). It is suspected that the lack of accepted measures for food security may hinder research in this field.

Conclusion

Adequate nutrition is needed to support growth and development and it is a basic human right to have adequate food and water. Yet many in the world lack access to safe food and water. This situation may be acute or chronic. The most immediate need is access to pure water to maintain hydration. Most previously well-nourished adults can live for 2 months without food as long as water is available. Water must be consumed within 2 days to maintain hydration status.

If this situation is chronic, then malnutrition is much more serious and often deadly. Malnutrition is typically linked with disease and outcomes may be poor even when food becomes available. These are the challenges of refeeding programs; success is often elusive. Malnourished individuals are often immunocompromised and are unable to digest and absorb the nutrients they need.

Malnutrition is of greatest concern in infants and children as their nutrient needs are highest and they are less able to

source and ingest foods. All children need access to nutrient-rich diets and these include high-quality protein, essential fatty acids, vitamins, and minerals. Many foods can provide these nutrients and local customs and tastes must be considered. Food that is not eaten provides no nutrient value.

GUIDE TO USING THE ENCYCLOPEDIA

Structure of the Encyclopedia

The material in the encyclopedia is arranged as a series of articles in alphabetical order.

There are four features to help you easily find the topic you're interested in: an alphabetical contents list, cross-references to other relevant articles within each article, and a full subject index.

1 Alphabetical Contents List

The alphabetical contents list, which appears at the front of each volume, lists the entries in the order that they appear in the encyclopedia. It includes both the volume number and the page number of each entry.

2 Cross-References

Most of the entries in the encyclopedia have been cross-referenced. The cross-references, which appear at the end of an entry as a See also list, serve four different functions:

i. To draw the reader's attention to related material in other entries.
ii. To indicate material that broadens and extends the scope of the article.
iii. To indicate material that covers a topic in more depth.
iv. To direct readers to other articles by the same author(s).

Example

The following list of cross-references appears at the end of the entry Critical Tracking Events Approach to Food Traceability.

> *See also*: Agribusiness Organization and Management. Food Chain: Farm to Market. Food Labeling. Food Law. Food Packaging. Food Security: Development Strategies. Food Security: Food Defense and Biosecurity. Food Security, Market Processes, and the Role of Government Policy. Food Security: Postharvest Losses. Global Food Supply Chains. Government Agricultural Policy, United States. Regulatory Conventions and Institutions that Govern Global Agricultural Trade

3 Index

The index includes page numbers for quick reference to the information you're looking for. The index entries differentiate between references to a whole entry, a part of an entry, and a table or figure.

4 Contributors

At the start of each volume there is list of the authors who contributed to that volume.

SUBJECT CLASSIFICATION

Agriculture and People

Agribusiness Organization and Management
Agricultural Cooperatives
Agricultural Ethics and Social Justice
Agricultural Finance
Agricultural Labor: Demand for Labor
Agricultural Labor: Gender Issues
Agricultural Labor: Labor Market Operation
Agricultural Labor: Supply of Labor
Agricultural Law
Agricultural Policy: A Global View
Analyses of Total Phenolics, Total Flavonoids, and Total Antioxidant Activities in Foods and Dietary Supplements
Changing Structure and Organization of US Agriculture
Climate Change, Society, and Agriculture: An Economic and Policy Perspective
Computer Modeling: Policy Analysis and Simulation
Consumer-Oriented New Product Development
Crop Insurance
Determining Functional Properties and Sources of Recently Identified Bioactive Food Components: Oligosaccharides, Glycolipids, Glycoproteins, and Peptides
Farm Management
Food Chain: Farm to Market
Food Labeling
Food Law
Food Marketing
Food Security, Market Processes, and the Role of Government Policy
Food Security: Development Strategies
Food Security: Food Defense and Biosecurity
From Foraging to Agriculture
Global Food Supply Chains
Government Agricultural Policy, United States
Human Nutrition: Malnutrition and Diet
Industrialized Farming and Its Relationship to Community Well-Being
Intellectual Property in Agriculture
International and Regional Institutions and Instruments for Agricultural Policy, Research, and Development
International Trade
Investments in and the Economic Returns to Agricultural and Food R&D Worldwide
Markets and Prices
Mathematical Models to Elaborate Plans for Adaptation of Rural Communities to Climate Change
Policy Frameworks for International Agricultural and Rural Development
Production Economics
Quantitative Methods in Agricultural Economics
Regulatory Conventions and Institutions that Govern Global Agricultural Trade
Rural Sociology
Safety of Street Food: Indonesia's Experience
Social Justice: Preservation of Cultures in Traditional Agriculture
Vitamins and Food-Derived Biofactors

Agriculture and the Environment

Agroforestry: Conservation Trees and Erosion Prevention
Agroforestry: Hydrological Impacts
Air: Confined Animal Facilities and Air Quality Issues
Air: Greenhouse Gases from Agriculture
Biodiversity and Ecosystem Services in Agroecosystems
Biodiversity: Conserving Biodiversity in Agroecosystems
Climate Change: Agricultural Mitigation
Computer Modeling: Applications to Environment and Food Security
Crop Pollination
Dust Pollution from Agriculture
Ecoagriculture: Integrated Landscape Management for People, Food, and Nature
Economics of Natural Resources and Environment in Agriculture
Energy and Greenhouse Gases Footprint of Food Processing
Land Use: Catchment Management
Land Use, Land Cover, and Food-Energy-Environment Trade-Off: Key Issues and Insights for Millennium Development Goals
Land Use: Management for Biodiversity and Conservation
Land Use: Restoration and Rehabilitation
Linkages of the Agricultural Sector: Models and Precautions
Market-Based Incentives for the Conservation of Ecosystem Services in Agricultural Landscapes: Examples from Coffee Cultivation in Latin America
Natural Capital, Ecological Infrastructure, and Ecosystem Services in Agroecosystems

Soil: Carbon Sequestration in Agricultural Systems
Soil: Conservation Practices
Soil Greenhouse Gas Emissions and Their Mitigation
Soil: Nutrient Cycling
Virtual Water and Water Footprint of Food Production and Processing
Water: Advanced Irrigation Technologies
Water Use: Recycling and Desalination for Agriculture
Water: Water Quality and Challenges from Agriculture
Weather Forecasting Applications in Agriculture
World Water Supply and Use: Challenges for the Future

Agriculture Products

Advances in Pesticide Risk Reduction
Agricultural Mechanization
Agroforestry: Complex Multistrata Agriculture
Agroforestry: Fertilizer Trees
Agroforestry: Fodder Trees
Agroforestry: Participatory Domestication of Trees
Agroforestry: Practices and Systems
Asian Aquaculture
Beef Cattle
Climate Change: Animal Systems
Climate Change: Cropping System Changes and Adaptations
Climate Change: Horticulture
Climate Change: New Breeding Pressures and Goals
Critical Tracking Events Approach to Food Traceability
Dairy Animals
Edaphic Soil Science, Introduction to
Fermentation: Food Products
Fermented Beverages
Food Engineering
Food Microbiology
Food Packaging
Food Safety: Emerging Pathogens
Food Safety: Food Analysis Technologies/Techniques
Food Safety: Shelf Life Extension Technologies
Food Security: Postharvest Losses
Food Security: Yield Gap
Food Toxicology
Forage Crops
Global Agriculture: Industrial Feedstocks for Energy and Materials
Green Revolution: Past, Present, and Future
Medicinal Crops
Organic Agricultural Production: Plants
Organic Livestock Production
Precision Agriculture: Irrigation
Public–Private Partnerships in Agroforestry
Root and Tuber Crops
Sensory Science
Simulation Modeling: Applications in Cropping Systems
Slum Livestock Agriculture
Small Ruminants in Smallholder Integrated Production Systems
Spices and Aromatics
Sugar Crops
Terroir: The Application of an Old Concept in Modern Viticulture
Tree Fruits and Nuts

Animal Health

Animal Health: Ectoparasites
Animal Health: Foot-and-Mouth Disease
Animal Health: Global Antibiotic Issues
Animal Health: Mycotoxins
Animal Health: Tuberculosis
Animal Welfare: Stress, Global Issues, and Perspectives
Biosecurity and Equine Infectious Diseases
Detection and Causes of Bovine Mastitis with Emphasis on *Staphylococcus aureus*
Emerging Zoonoses in Domesticated Livestock of Southeast Asia
Invasive Aquatic Animals
Marek's Disease and Differential Diagnosis with Other Tumor Viral Diseases of Poultry
Poultry and Avian Diseases
Quarantine and Biosecurity
Swine Diseases and Disorders
Vaccines and Vaccination Practices: Key to Sustainable Animal Production
Zoonotic Helminths of Livestock

Plant Health

Climate Change and Plant Disease
Emerging Plant Diseases
Integrated Pest Management in Tree Fruit Crops
Invasive Species: Plants
Mineral Nutrition and Suppression of Plant Disease
Pathogen-Tested Planting Material
Plant Abiotic Stress: Salt
Plant Abiotic Stress: Temperature Extremes
Plant Abiotic Stress: Water
Plant Biotic Stress: Weeds
Plant Disease and Resistance
Plant Health Management: Biological Control of Insect Pests

Plant Health Management: Biological Control of Plant Pathogens
Plant Health Management: Crop Protection with Nematicides
Plant Health Management: Fungicides and Antibiotics
Plant Health Management: Herbicides
Plant Health Management: Pathogen Suppressive Soils
Plant Health Management: Soil Fumigation
Plant Health Management: Soil Solarization
Quarantine and Biosecurity
Soil Fertility and Plant Nutrition

Agriculture and Science

Advances in Animal Biotechnology
Agbiotechnology: Costs and Benefits of Genetically Modified Papaya
Biotechnology Crop Adoption: Potential and Challenges of Genetically Improved Crops
Biotechnology: Herbicide-Resistant Crops
Biotechnology: Pharming
Biotechnology: Plant Protection
Biotechnology: Regulatory Issues
Breeding: Animals
Breeding: Plants, Modern
Cloning Animals by Somatic Cell Nuclear Transplantation
Cloning: Plants – Micropropagation/Tissue Culture
Domestication of Animals
Domestication of Plants
Genebanks: Past, Present, and Optimistic Future
Genomics of Food Animals
Genomics: Plant Genetic Improvement
Heterosis in Plants
Plant Cloning: Macropropagation
Plant Virus Control by Post-Transcriptional Gene Silencing
Regulatory Challenges to Commercializing the Products of Ag Biotech
Stem Cells
Transgenic Methodologies – Plants

PREFACE

Food is absolutely necessary for human existence, yet for most in wealthy nations it is largely taken for granted because of its abundance. Sufficient food is a concern, however, for about 1 billion of the earth's inhabitants today who often go to bed hungry. Food security in a broad sense is becoming a worry of the future for those who understand the limitations of our earth's ecosystems. Malthusian prophecies have so far been wrong, but there is growing concern that we are rapidly reaching the point where feeding the world's growing and richer population will be at the cost to our environment that is unacceptable. In the next few decades we face the challenge of growing more food, with less water, with less fertilizer on less land – because of the growth of urban areas on prime agriculture land. We also face the largely unknown consequences that global warming will have on agricultural production. During the last century agricultural scientists were able to bring cutting-edge science into traditional agricultural practices and increase food production sufficiently to prevent global food shortages. The hope that new scientific discoveries will provide the means to keep ahead of world food demand is complicated by a growing public discomfort with biotechnology being applied to food production.

The concept of services being provided by the ecosystems of the earth is a fairly recent attempt to understand and place value on functions of natural lands that have historically been assumed to have few limits. In the past, if more food was needed, new lands were converted from forests or steppe lands into farm land and new water systems developed to provide the water needed for agriculture. When human populations were low our activities were largely buffered by the abundance of forest and steppe, but too late, we are beginning to understand that these provisioning services of our ecosystems are being overused and are no longer buffered by the abundance of wild lands and waters. We are rapidly losing our planet's biodiversity, irreplaceable ground water is being unsustainably consumed, and major river systems are being overused and polluted. Our oceans, the last place on the planet that still support our hunter and gathering traditions may not be able to sustain these activities into the future. And, food production and processing activities contribute to the greenhouse gas emissions that are rapidly warming our planet. Agriculture is the single greatest user of the earth's land and water resources. In the concept of ecosystem services, provisioning or providing food for all organisms is one of the services provided by ecosystems. Human population growth has and will continue to overtax the ecosystems we inhabit. The ultimate outcome of this major diversion of nature's resources into provisioning the human species is unknown, but it is critically important for us to understand what we must do to sustain our planet.

The breakthrough discovery about 10 000 years ago that plants and animals could be bred to provide a more abundant and secure food source was the foundation upon which all other human activities were able to flourish. Activities other than finding food now became possible and our diverse cultures were able to develop because of agriculture. Until fairly recently, however, the majority of the population of most nations was still directly involved in producing food. Mechanization of agriculture and continued improvements in genetics, fertilizers, and pesticides made food production very efficient in developed nations. In the United States, the leading nation in value of agricultural exports, less than 2% of the workforce is currently employed in producing food. The United States, however, is alone among the most populous nations of the world in having such a small population employed as farmers. In countries such as China, India, Indonesia, and Nigeria the majority of people are rural and involved in agriculture either directly or indirectly. But, as food production becomes more efficient in these countries, and as wages increase in other sectors, a major shift is occurring from rural to urban occupations. This revolution is potentially as important in affecting our cultures and community structures as was the development of agriculture. Many nations are currently experiencing a very rapid transition from rural to urban living with all of the social and logistic problems associated with such rapid structural changes. While this transition in our social and cultural structures is a broad subject, it does have significant impacts on agriculture and our food systems. To mention just a few, agriculture labor, food transport, food safety, and access to healthy food.

There is genuine concern among agricultural scientists that human populations and changing diets are outpacing our ability to meet the increasing food needs of the planet. In the first iteration by Academic Press in 1994 of the *Encyclopedia of Agricultural Science*, Noble Prize Winner Normal Borlaug wrote in its forward:

> Had the world's 1990 food production been distributed evenly, it would have provided an adequate diet (2350 calories, principally from grains) for 6.2 billion people – nearly one billion more than the actual population. However, had the people in Third World countries attempted to obtain 30% of their calories from animal products – as in the United States, Canada, or European Economic Community countries – a world population of only 2.5 billion people could have been sustained – less than half of the present world population.

The issue raised by Dr. Borlaug is probably the most important challenge we face. Human behavior and the food choices of consumers will determine the outcome of the race between food supply and population. Population control has been advocated for decades, and in some cases has become part of national policy, but the world's population continues to grow. Science breakthroughs cannot solve our food security and environmental quality challenges if consumers reject food that is not traditionally produced. Likewise, if meat products and other inefficiently produced food continue to be in high demand by consumers, there will be increased pressure on our food production systems. As supplies become short, prices rise. While this may be good for farmers, high food prices and food shortages will probably undermine our efforts to preserve the

world's remaining arable land as natural lands. We must change human behavior to solve the problems we face.

Food choices, nutrition, diets, food cultures, water and air quality, GMOs, global warming, food security, and similar topics are daily in the news throughout the world. We are all concerned about these issues, yet with all of the information easily available in the popular media about food there seems to be too little informed discussion on these various topics. In planning the *Encyclopedia of Agriculture and Food Systems* the editorial committee chose to organize the topics primarily by issues, rather than to focus on a traditional topic approach. We organized the issues that would be discussed in the chapters around the broad topics of Agriculture and People, Agriculture and the Environment, Agricultural Products, Plant Health Management, Animal Health Management, and Agriculture and Science. The issues raised in this preface are the ones that we felt needed to be addressed in this encyclopedia.

The associate editors joined me in the development of topics for the encyclopedia and were responsible for working with the authors – they deserve particular recognition. I was fortunate to be joined by a very distinguished group of colleagues who, I hope, are still friends. They spent much more time and effort in bringing this project to completion than any of us anticipated. I want to thank our authors who while overly committed and overworked, fulfilled their commitments to contribute to this work. I have been impressed with the quality of their contributions. The editorial staff of Elsevier have had the professionalism and patience to work with scientists who do not work under the same time and budget constraints that the staff work. I want to particularly thank Kristi Gomez, Donna de Weerd-Wilson, and Simon Holt who, each in succession, oversaw this effort, and I especially thank the project managers, who worked directly with me, and the associate editors, Kate Miklaszewka-Gorczyca, Will Bowden-Green, and Sam Mahfoudh.

Glossary

Community social fabric Refers to social organization, the features of a community that reflects its stability and quality of social life. Impacts on community social fabric are seen in social indicators such as population change; social disruption indicators; educational attainments and schooling quality; changes in social class structure; health status; and changes in local governance.

Family farm A farm operation where the farm household owns and controls the majority of farm production factors, land, labor, capital, technology, and management.

Industrial farm A nonhousehold-based farm production unit, with absentee ownership and control over production factors.

Marketing contracts The mechanism used by farm operators to reduce their exposure to market price swings; these contracts stipulate a commodity price or pricing mechanism for delivered goods and are used mainly for crop and dairy commodities.

Organizational changes in farming An increase in the relative proportion of hired to family labor, greater use of incorporation as a form of legal organization, and the movement toward a more integrated industry from farm to grocery, whose 'hallmark' is 'contract production and vertical integration.'

Organizational measures of industrialized farming Vertical integration of corporations into farming; contract farming arrangements; absentee ownership of production factors; dependency on hired labor; operation by farm managers, as opposed to material operation by family members; and legal status as a corporation.

Production contracts Mechanisms that involve cost-sharing arrangements and payment for farm operators' services usually for livestock production except for dairying.

Socioeconomic well-being Refers to standard measures of economic performance (employment, income, and business activity) and to a broader range of socioeconomic indicators used by sociologists to tap material conditions of families and populations (family poverty rates and income inequality).

The industrialization of farming The transformation whereby farms have become larger-scale, declined in number, and integrated more directly into production and marketing relationships with processors through vertical or contractual integration.

Vertical integration Operation of farms by firms that also operate in at least one other stage of the food chain, such as input supply, processing, and marketing.

Introduction

Public concern about the consequences of nonfamily owned and operated, industrialized farms for communities dates back to the 1920s (Boles and Rupnow, 1979). (Boles and Rupnow (1979, p. 471) state that public concern about corporate influence in farming began in the 1920–30 period when concern about large, publicly held corporations centered on fears about the effect of mechanization, foreclosure of farm land mortgages held by corporations, and corporate monopoly of land.) The first published research on the topic appeared in the 1930s. Since then, government and academic researchers have produced numerous studies showing the potential for adverse impacts on community life. The bulk of evidence indicates that public concern about the detrimental community impacts of industrialized farming is warranted. This article summarizes results from more than five decades of research that has investigated the relationship between nonfamily industrialized farming and community well-being. The purposes of this article are: To document the types of studies that have been conducted on the topic; to delineate their results as to whether adverse consequences were found; and to document the aspects of community life that may be jeopardized by industrialized farming. This article is grounded in Lobao's (1990) longstanding research on farm change and its impacts on communities and families (Barlett *et al.*, 1999; Belyea and Lobao, 1990; Kenney *et al.*, 1989; Lasley *et al.*,1995; Lobao (Reif), 1987; Lobao, 1990; Lobao (Reif) and Jones, 1987; Lobao and Meyer, 1995a,b, Meyer and Lobao, 1997; Lobao and Schulman, 1991; Lobao *et al.*, 1993; Lobao and Thomas,

1992, 1988) as well as her research on the broader topic of community development. (Lobao, 1993a,b,c, 1996, 1998; Lobao and Rulli, 1996; Lobao *et al.*, 1999). She updated this research in 2000 (Lobao, 2000), which was further updated in 2006 (Stofferahn, 2006), and which was updated and published in 2008 (Lobao and Stofferahn, 2008). This article further updates the research on the topic, and it is based on a systematic article of 56 studies on the topic of industrialized farming and community well-being.

The industrialization of farming refers to the transformation whereby farms have become larger-scale, declined in number, and integrated more directly into production and marketing relationships with processors through vertical or contractual integration (Drabenstott and Smith, 1996, p. 4). In the past two decades, farms in the farming-dependent Heartland states (The states forming the nation's farm heartland extend from the Mississippi River to the Rocky Mountains and from Texas to Canada. These states are Colorado, Iowa, Kansas, Minnesota, Missouri Montana, Nebraska, New Mexico, North Dakota, Oklahoma, South Dakota, and Wyoming (Barkema and Drabenstott, 1996, p. 1). More than two-thirds of the nation's farm-dependent counties are located in these states.) declined by roughly one-fourth, whereas average acreage grew by one-fourth to approximately 750 acres (Barkema and Drabenstott,1996, p. 62). As the number of farms declines, production becomes concentrated on larger farms. Nationally, small farms (defined here as those having annual gross sales of less than US$50 000) made up nearly three-quarters of the nation's farms in 1995 but they produced only approximately 8% of sales, whereas the top 2% of farms (those with sales of over a half million dollars annually) accounted for 44% of all sales (Sommer *et al.*, 1998, p. 10). Half of the nation's agricultural sales are produced by 3% of farms (Sommer *et al.*, 1998, p. 8).

Accompanying the growth of scale of operations are organizational changes in farming. These include an increase in the relative proportion of hired to family labor and greater use of incorporation as a form of legal organization. (In 1995, more than 98% of the nation's 2.07 million farms were classified as family operations. A total of 91% were sole proprietorships and 5% were partnerships. Only 3% of all farms were incorporated, and of these, 86% were considered family-held corporations by United States Department of Agriculture (USDA) as they had 10 or less stockholders (Sommer *et al.*, 1998, p. iv). Another organizational shift is the movement toward a more integrated industry from farm to grocery, whose 'hallmark' is "contract production and vertical integration that is linking farmers, food processors, seed companies, and other agribusiness" (Barkema and Drabenstott, 1996, p. 64). Vertical integration refers to operation of farms by firms that also operate in at least one other stage of the food chain – such as input, supply, processing, and marketing. In addition to their direct involvement in farm production, agribusiness firms contract with farmers for goods and services. Two types of contracting arrangements should be distinguished. Marketing contracts are used by independent operators to reduce their exposure to market price swings; these contracts stipulate a commodity price or pricing mechanism for delivered goods and are used mainly for crop and dairy commodities. Production contracts involve cost-sharing arrangements or payment for operators' services usually for livestock production except for dairying. On farms using production contracts, the largest share of farm sales accrues to the contractor (an agribusiness processor and/or producer), with the operator generally receiving a fixed fee for services (Sommer *et al.*, 1998, pp. 16–17). Production contracts extend agribusiness firms into direct farm production using the vehicle of the local farmer. To sociologists, production contract farms are an integral component of the agribusiness chain in which agribusiness firms, depending on corporate strategy, may enter farming through direct operation of their own units or through employing local farmers to participate in production homework. Sociologists are concerned with contract farming because of the risks it poses to agrarian social structure, communities, and families. (Sociologists are concerned with contract farming insofar that: it alters agrarian social structure by creating a segment of farmers who are the structural equivalent of factory production homeworkers; it extends the influence of industrialized farming in a community; and it erodes formally independent operators' autonomy in direct production, farm decision-making, and control over assets. Sociologists also are concerned with the general well-being of contractees (operators) and their families given their asymmetrical relationship in bargaining power with agribusiness firms.)

In classifying farms as 'industrialized' or 'family,' social scientists distinguish between the construct (an ideal-type concept) and its actual measurement (variables used to define the concept in practice). Different classifications of farms have been developed over the years because the structure of agriculture is continually changing. The term 'farm structure' or 'agricultural structure' refers to a broad set of characteristics that describe US farms, as well as the distribution of farm production resources and returns to those engaged in farm production activities (Sommer *et al.*, 1998, p. 6). Sommer *et al.* (1998, p. 6) provide a useful overview of the criteria used to classify farms. For sociologists, family farming is identified by whether the family unit owns a majority of capital resources, such as land, machinery, buildings, makes the majority of managerial decisions, and provides the bulk of labor (Goss *et al.*, 1980). Social scientists often use farm scale as a proxy measure to classify farms, because it is simple, clear, and often correlated with organizational characteristics of units. A recent USDA article classifies 'commercial farms' as those with US $50 000 or more in gross sales and 'small farms' as those with gross sales of less than US$250 000 (Sommer *et al.*, 1998, p. 69). Family farms (organized as sole proprietorships, partnerships, or family corporations) with gross sales of more than US$25 000 are classified as 'large-family farms,' whereas 'nonfamily farms' are any farms organized as nonfamily corporations, cooperatives, and farms operated by hired managers (Sommer *et al.*, 1998, p. 72). 'Family' farms and 'industrialized' farms are constructs at opposite ends of the farm continuum. To sociologists, the construct 'family farm,' is that where the farm household owns and controls the majority of farm production factors, land, labor, capital, technology, and management. At the other end of the farm continuum, the construct, 'industrial farm,' refers to a nonhousehold-based production unit, with absentee ownership and control over production factors. As with nonfarm firms, industrialized farms have a division of labor among owners, managers, and

labor with different groups of people assigned to different positions in the production process. Industrial farms "...are owned by one group of people, managed on a daily basis by another person or group, and worked by yet another group" (Browne *et al.*, 1992, p. 30). Between these 'ideal-type' descriptions of family and industrialized farms are other arrangements in organizing farming, such as part-owner farming (a form of family farming where the operator both owns and rents the land). Again, these are 'ideal-type' constructs, whose specific definition and measurement must depend upon the time period and public context.

When social scientists refer to 'industrialized' farms, they invariably are referring to both scale and organizational characteristics of the farm unit. (Social scientists measure industrialized farming by both scale and organizational variables. Scale is usually measured by sales and sometimes by acreage and real estate and for livestock operations, animal inventory. The actual dollar value for scale indicators used by analysts to indicate a 'large-scale' farm will obviously vary by the time period of study. In addition, what is considered a 'large-scale farm' also varies by regional context and commodity. Organizational measures of industrialized farming include vertical integration of corporations into farming; production contract farming arrangements; absentee ownership of production factors; dependency on hired labor; operation by farm managers, as opposed to material operation by family members; and legal status as a corporation (family or nonfamily) or syndicate.) In general, but not always, scale will coincide with organization. That is, large-scale farms (relative to smaller farms) are more dependent on hired labor and managers and more likely to have absentee owners, to be incorporated, and to be vertically integrated with agribusiness. For example, in 1995, mean gross sales of corporate farms were US$576 925 as compared with US$54 287 for sole proprietorship farms and US$218 795 for farms organized as partnerships (Sommer *et al.*, 1998, p. 15). Farms with production or marketing contracts also tend to be larger. In 1995, farms with marketing contracts (approximately 11% of all farms) had mean gross sales of US$242 888; whereas farms with production contracts (2.3% of all farms) had mean gross sales of US$617 858 (Sommer *et al.*, 1998, p. 12). For the purposes of this article, the umbrella term 'industrialized farm' is used to refer to both scale and operating characteristics of industrialized farms. Where it is useful and feasible to do so, a distinction is made between between scale and operating characteristics.

This article is organized into four sections. First, the article discusses the history of government and academic concern about the risks of industrialized farming for community well-being, from the 1930s to the present. Second, the article summarizes the findings from Lobao's research and that of her colleagues. Third, the article findings from five decades of social science research. It is divided into several subsections discussing, respectively, research issues involved in analyzing industrialized farming and community impacts, focusing on indicators of industrialized farming and types of consequences that a summary evaluation must consider; the various research designs used to assess the consequences of industrialized farming; and a summary of the results of past studies as to whether detrimental impacts were found. Eventually, the article ends with summary and conclusion.

It should be noted that public concern about industrialized farms extends beyond the well-being of states and their communities. Rather, public as well as academic concern extends to national food system issues, such as agribusiness concentration, consumer health, food safety, and sustainability of the national ecosystem. The immediate effects of industrialized farms, however, are on the day-to-day lives of people residing in the places where these farms are located. It is also at this level that social scientists have conducted a great deal of research over a long period of time. For these reasons, this article deals with the consequences of industrialized farming for well-being at the community level.

History of Public, Government, and Academic Concern with the Consequences of Industrialized Farming

More than a half century of research centers on the potential detrimental social consequences of industrialized farming. Since 1930s, the government and academic researchers have investigated the extent to which large-scale, industrialized farms adversely affect the communities in which they are located. One of the first series of studies was conducted by a sociologist, Tetreau (1938, 1940), who found that large-scale, hired labor-dependent farms were associated with poor social and economic well-being in rural Arizona communities.

In the early 1940s, the USDA sponsored a research project on the effects of industrialized farming using a matched-pair of two California communities, Arvin where large, absentee-owned, nonfamily operated farms were more numerous, and Dinuba, where locally owned, family operated farms were more numerous. The article on this project was prepared by Walter Goldschmidt, a USDA anthropologist. The purpose of the study was to assess the consequences of a California law with a provision placing acreage limitations on large farms located in California's Central Valley, so as to support family-size farms in the region. Goldschmidt (1978a, p. 458) notes that "The comparative study of Arvin and Dinuba was designed to determine the social consequences that might be anticipated for rural communities if the established law was applied or rescinded."

In this article, Goldschmidt (1978a) systematically documented is the relationship between large-scale farming and its adverse consequences for a variety of community quality of life indicators. Goldschmidt (1978a) observed that, relative to the family farming community, Arvin's population had a small middle class and high proportion of hired workers. Family incomes were lower and poverty was higher. There were poorer quality schools and public services, fewer churches, civic organizations, and retail establishments. Arvin's residents also had less local control over public decisions, or 'lack of democratic decision-making,' as the local government was prone to influence by outside agribusiness interests. By contrast, family farming Dinuba had a larger middle class, better socioeconomic conditions, high community stability, and civic participation. Goldschmidt's review was eventually published as Congressional Testimony (1968) and as a book (1978a). Goldschmidt's conclusion that large-scale industrialized farms create a variety of social problems for communities has been confirmed by a number of subsequent studies. One criticism

of Goldschmidt's (1978a) research was published by agricultural economists Hayes and Olmstead (1984). They did not challenge Goldschmidt's (1978a) conclusion that large-scale, industrialized farms have adverse community impacts. Rather they argued that Arvin and Dinuba were not as closely matched research sites in the 1930s as Goldschmidt had intended. Nearly four decades after Goldschmidt's study, the state of California, through its Small Farm Viability Project (1977, pp. 229–230), affirmed Goldschmidt's conclusions by revisiting Arvin and Dinuba. They concluded that: "The disparity in local economic activity, civic participation, and quality of life between Arvin and Dinuba...remains today. In fact, the disparity is greater. The economic and social gaps have widened. There can be little doubt about the relative effects of farm size and farm ownership on the communities of Arvin and Dinuba."

As the US agricultural structure has evolved toward larger and fewer farms, government and academic researchers have continued to investigate the extent to which large-scale, nonfamily owned and operated industrialized farms adversely affect communities. Congress has conducted inquiries, such as that by the Senate Subcommittee on Monopoly dealing with Corporate Secrecy and Agribusiness, in which rural sociologists and agricultural economists provided testimony in 1973 about the dangers to communities posed by increasing corporate control of agriculture (Boles and Rupnow, 1979, pp. 468–469). The Office of Technology Assessment (OTA), concerned that the relative growth of large-scale industrialized farms might have adverse impacts on communities, commissioned a series of research papers on the topic. The OTA research came as a request from Congress and was published first as a review (OTA, 1986) and later as a book (Swanson, 1988). Federal and state funding has been directed to at least two Agricultural Experiment Station projects that assess the community consequences of large-scale, nonfamily farms: Project S-148 'Changing Structure of Agriculture: Causes, Consequences, and Policy Implications' (1982–86); and Project S-198 'Socioeconomic Dimensions of Technological Change, Natural Resource Use, and Agricultural Structure' (1986–90). The later project resulted in a monograph on the consequences of industrialized farming for communities (Lobao, 1990) among other publications.

In the 1990s, public concern with industrialized farming has centered particularly on large integrated livestock producer/processor enterprises. Recent studies supported by the NCRCRD (1999), the University of Missouri Agricultural Experiment Station (Seipel *et al.*, 1998, 1999) and Duke University Medical School (Schiffman, 1998) have documented a variety of adverse impacts of these enterprises on communities, households, and individuals.

In summary, there has been more than 50 years of public, academic, and government concern that large-scale, industrialized farms jeopardizes community well-being. This concern has resulted in numerous studies, in government-sponsored reviews, and in congressional hearings. In the 1990s, public concern with industrialized farming has increased due to the problems posed by large-scale animal confinement operations. Social scientists have responded to this increased public concern by initiating a number of recent projects, leading to a new generation of literature on the community consequences of industrialized farming.

Research by Lobao and Colleagues

The most recent, comprehensive sociological study on the effects of industrialized and family farming on communities was conducted by Lobao (1990). This study examined relationships across more than 3000 US counties. The study used both farm scale and organization to measure farm structure; examined direct and indirect consequences of farming patterns; and examined long-term and immediate relationships for two time periods, 1970–80. To measure community outcomes, the study focused mainly on socioeconomic well-being indicators (median family income, poverty, and income inequality between families measured by the Gini coefficient. The Gini coefficient is used by the federal government to document income inequality in the US and is the measure used most frequently in recent studies of economic development across spatial units such as counties (Lobao *et al.*, 1999)) but also included of community social disruption (births-to-teenagers) and health status (infant mortality). The study examined the effects of three different community farm structures: 'smaller family farming' (small, part-time family farms); 'larger family farming' (moderate-size, capital-intensive, family operated units using little hired labor), and industrialized farming (large-scale, hired-labor-dependent farms).

The community farming structures were constructed based on the research by Wimberley (1987). Each of the measures of farm structure was a composite of scale and organizational indicators, created through a statistical technique called factor analysis. Multivariate statistical methods, regression, and discriminant analysis, were used to analyze the effects of the three farm structures net of other community conditions, including nonfarm industrial employment, establishment size of local businesses, human capital, and demographic characteristics of the population (educational attainments, ethnicity), unemployment, social welfare payments, unionization, and spatial factors, such as region of the country.

The findings were the following. There was consistent support that moderate-sized family owned and operated farms benefit communities. Counties where these types of farms (i.e., larger family farming) predominated had better socioeconomic well-being (lower family poverty, higher median family income, lower unemployment, and lower infant mortality). The beneficial effects of this family farming were found across the US, for two time points, 1970 and 1980. Moreover, this type of farming continued to result in beneficial effects over time. Counties where larger family farming was greater in 1970 continued to have better socioeconomic well-being over time. This study indicates that the 'high road' to community development is a farming system based on moderate-sized family operations. Such farming not only increases aggregate well-being, as indicated by income levels, but it also sustains a larger middle class, as indicated by lower income inequality and poverty, and thus allows more families to benefit from the income produced.

Where industrialized farming was greater, however, there were mixed effects on community well-being, either detrimental or no statistically significant impacts. For example, industrialized farming had no relationship with family poverty or median family income at either of the two single time points (1970 and 1980). Industrialized farming, however, was

related to higher income inequality at both time points, and also to lower family income, higher poverty, and higher income inequality across time, over the decade from 1970 to 1980 (i.e., counties with greater industrialized farming in 1970 experienced relative declines in socioeconomic well-being over the decade). The finding that industrialized farms are associated with high income inequality indicates that this farming segments social class structure by polarizing families into richer and poorer income groups. Income polarization is related to other social problems, such a crime and other breakdowns in the social fabric of the community. The study also found that where very small farms predominated, well-being was poorer. This indicates that researchers should distinguish between small and moderate family operated units in assessing consequences for well-being. Smaller family farming tends to predominate more in the South.

As would be expected in a postindustrial society, nonfarm manufacturing and service employment were stronger predictors of community well-being than farming. It is important to note, however, that the study found that farming, nonfarm industry, and other local characteristics were interrelated, mutually sustaining a population in a locale. (That farming has a smaller impact on community well-being than does nonfarm industry is expected even for communities highly dependent on farming. Farming is interrelated with local nonfarm industry and other sectors, forming a community livelihood strategy which sustains a population in a locale. Communities where larger family farming predominated had a much higher wage, durable manufacturing employment, and greater employment in local schools and retail industries. Communities where industrialized farming predominated had greater employment in lower wage manufacturing such as food processing, less employment in education, health, and retail services, a higher minority population, and provided relatively higher per capita benefits to welfare recipients.) Good quality farms and high quality local employment were interrelated, with 'larger family farming' associated with greater employment in high wage manufacturing and other beneficial sectors. The study offered consistent support that when farming is an economic development strategy of choice, moderate-sized family farms are best for communities.

This research on farming systems and community and regional well-being has been elaborated in other reviews (Kenney *et al.*, 1989; Lobao, 1987, 1993c, 1996, 1998; Lobao and Jones, 1987; Lobao and Schulman, 1991; Lobao *et al.*, 1993; Lobao and Thomas, 1992).

One of the most recent sociological analyses on industrialized farming and inequality is that conducted by one of Lobao's students (Crowley, 1999). The methodology used in the study is similar to that followed in Lobao (1990), but the indicators of farm structure differ. She analyzed the effects of farm concentration using several indicators (concentration of land, value of land and buildings, and the value of equipment and machinery, indicators measured by the Gini coefficient), and data for all (1053) counties in the North Central US (Illinois, Indiana, Iowa, Kansas, Michigan, Minnesota, Missouri, Nebraska, Ohio, North Dakota, South Dakota, and Wisconsin). She analyzed consequences of these dimensions of farm-sector concentration for local levels of family poverty and family income inequality net of other community characteristics. In counties where farm-sector concentration was higher (i.e., a few large farms held a disproportionate share of local property in land and real estate), there was significantly higher poverty among families and significantly greater income polarization between families. Moreover, where farm concentration was higher, residents had lower education.

In the 2004 study, Crowley and Roscigno documented how concentration of agricultural resources shapes rural community stratification through the political economic process. In addition to measures of farm sector resource concentration, measured by the Gini coefficient, and labor endowment (percentage of county work force employed in core, extractive, competitive, and state sectors), they included measures of political process (proportion of votes in presidential election for Democratic Party, average household payment rates, average per farm county level spending on agricultural assistance), and worker power attributes (percentage of manufacturing employees that are unionized, proportion of population that are a minority, percentage of population, aged 25+ years with a high school diploma, and proportion of labor force unemployed). Using data for all (1053) counties in the North Central US, it was found that dimensions of farm sector concentration shape both poverty and inequality. Furthermore, they found that farm sector concentration is explained by political economic processes, and these processes mediate the negative effects of land concentration on economic well-being. In particular, they found that relative to large-scale farms, capital concentration promotes government spending that benefits large farms, whereas it blocks government or labor-market programs that assists farmers whose farms it consumes and farm workers it exploits. These attempts are evident by the increased funding for agricultural research which benefits large farms, decreased redistribution efforts through transfer payments to benefit small farms and workers, decreased political consciousness through lower levels of Democratic Party support, and reduced labor power through lower unionization rates and education and higher unemployment and minority representation.

To provide a balanced assessment of the consequences of industrialized farming, it is useful to review the past findings of other investigators, using different methodologies, for different time periods, and from different disciplines. In the Section Review of Past Research on Industrialized Farming and Well-Being, the types of studies conducted on the relationship between industrialized farming and community well-being and their conclusions are discussed. On balance, the social science evidence accumulated from these and other studies supports public, academic, and government concern about the potential risks of industrialized farming. Recent research indicates that the public's welfare is at risk in at least four major areas. Industrialized farming (1) has a detrimental impact on certain aspects of socioeconomic well-being; (2) disrupts the social fabric of communities; (3) poses environmental threats where livestock production is concentrated; and (4) is likely to create a new pattern of 'haves and have nots' in terms of agricultural production, whereby some communities gain large, industrialized farms (and attendant social problems), and others lose their farming base as production becomes concentrated elsewhere in the state and regional economy. (Drabenstott and Smith, 1996, p. 4)

Review of Past Research on Industrialized Farming and Well-Being

Over the past half century, numerous studies, spanning different time periods and regions of the county have tended to find that large-scale industrial farming has detrimental community impacts. This does not mean that every study has produced these results, but rather that empirical evidence accumulated over the years shows a repeated trend that large-scale industrialized farms have adverse impacts on a number of different indicators of community well-being and that this trend is sufficiently established in the social sciences, to the point that almost all sociological studies begin with the working hypothesis (research expectation) that large-scale industrial farms will have adverse community effects. The extent to which past research supports this hypothesis is discussed in the Section Research Issues Involved in Analyzing Industrialized Farming and Its Community Impacts. It should be stressed that no single study can provide a definitive answer as to whether large-scale industrialized farming will or will not adversely affect public well-being in any particular region or state. This is due both to the complexity of the research question and to the lack of existing data required to fully analyze it. At best, a single study can assess the extent to which certain indicators of industrialized farming have adverse affects on certain indicators of community well-being in certain places and time periods. Therefore, the most comprehensive answer to the question of whether industrialized farming adversely affects public well-being comes not from a single study but from assessing the conclusions of decades of past research.

Research Issues Involved in Analyzing Industrialized Farming and Its Community Impacts

To adequately assess the consequences of large- scale industrial farming, the following issues about indicators of industrialized farming and types of consequences must be considered.

Industrialized farming should be analyzed using scale as well as indicators of farm organization. Scale is usually measured by sales or sometimes acreage. As a measure of industrialized farming, scale is limited for several reasons: Family owned and operated farms may be large scale owing to technology; scale alone does not capture organizational features of industrialized farming, such as absentee ownership and nonfamily control over production, that are thought to put communities at risk. Organizational measures of industrialized farming include: Vertical integration of corporations into farming; contract farming arrangements; absentee ownership of production factors; dependency on hired labor; operation by farm managers, as opposed to material operation by family members; and legal status as a corporation. With regard to legal status, family and nonfamily-held corporations should be distinguished. (It should also be recognized that farms may be incorporated because of family farmers' interests in estate planning, greater assurance of business continuity, limited liability, and income tax advantages.)

To adequately assess consequences for community well-being, the full array of outcomes should be considered. Research points to three major sets of consequences of industrialized farming in a community: impacts on socioeconomic well-being, community social fabric, and environment.

Socioeconomic well-being refers to standard measures of economic performance (essentially employment, income, and business activity) and to a broader range of socioeconomic indicators used by sociologists to tap material conditions of families and populations (family poverty rates and income inequality).

Community social fabric refers to social organization – the features of a community that reflects its stability and quality of social life. Impacts on community social fabric are seen in social indicators such as population change; social disruption indicators (crime rates, births-to-teenagers, social-psychological stress, community conflict, and interference with enjoyment of property); educational attainment and schooling quality; changes in social class structure (decline of local middle class and in-migration of low-wage workers); health status, such as mortality rates; civic participation (e.g., declines in church attendance, voluntary organizational membership, and voting); and changes in local governance, such as loss of local control over community decision-making, and resource/fiscal pressures on local government, such as those due to increased need for social services and diversion of public funds to subsidize agribusiness development.

Environmental indicators include quality of water, soil, and air, energy usage, and environmentally related health conditions.

Industrialized farming has both direct and indirect consequences for community well-being. Both sets of consequences should be considered. Industrialized farms directly influence community well-being: Through the quantity of jobs produced and the earnings' quality of those jobs; by the extent to which these farms purchase inputs and sell outputs locally; by affecting the quality of local environmental conditions; and by affecting local decision-making about economic development and other public-interest areas relevant to community quality of life.

First-order, indirect effects on local economic performance and general socioeconomic conditions occur because the quantity and quality of jobs plus purchases affect total community employment, earnings, and income (e.g., economic multiplier effects), the local poverty rate, and income inequality. First-order, indirect effects on local social fabric occur because the quantity of jobs created by industrial farms affects total community population size; the quantity and quality of jobs affect social class composition, such as a when an increase in hired farm workers reduces the proportion of the local middle class; local control over community decision-making may erode or become conflictual, as the interests of industrialized farmers and absentee owners are detached from those of local residents.

Second-order, indirect effects on local social fabric work through first-order effects cited above. Population size and social class composition are related to indicators of community social disruption, such as crime, family instability, the high school dropout rate, and conflict resulting in civil suits; local demand for schooling, public assistance, health, and other social services; and the property tax base (Boles and Rupnow, 1979; Freudenburg and Jones, 1991; Murdock *et al.*, 1988;

NCRCRD, 1999 (Rapid increases in population size and poorer social class composition tend to be related to the indicators of social disruption noted and also place increased demands on local schooling and other social services. Population decline reduces local demand for services and the property tax base.). Decline of local control over community decision-making creates problems associated with poor governance, such as the potential for diversion of public resources toward financial incentives supporting the interests of agribusiness developers over the community at large; and the loss of public and private revenues to support local schools, community services, and infrastructure, which contributes to a downward spiral of community social and economic conditions.

The direct and indirect paths by which industrialized farming may affect community well-being are delineated in various studies, including Boles and Rupnow (1979), Lasley *et al.* (1995), Lobao (1990), MacCannell (1988), and the NCRCRD (1999).

Differences in impacts for diverse social groups within the community must be considered. Changes in farming affect social groups differently, depending upon their age, class position, and residents' proximity to industrialized farms. The elderly and poor are affected by rising costs of housing and services whenever large corporations migrate to a rural community (Summers *et al.*, 1976). Within communities with large confined animal-feeding operations (CAFOs), residents who live closer to the operation review inability to enjoy their properties and physical and psychological problems associated with odor (Schiffman *et al.*, 1998; Wing and Wolf, 1999; Reisner *et al.*, 2004; Constance and Tunistra, 2005). Property closer to CAFOs has been found to fail to appreciate in value relative to places further away (Seipel *et al.*, 1998). Income generated by industrialized farming (relative to family farming and over time) also appears less likely to filter down to families of different social classes. As noted, Lobao (1990) and Crowley (1999) observed that income inequality was higher in communities where industrialized farming was greater.

There are long-term as well as short-term consequences of industrialized farming for communities and for regional development within a state. Industrialized farming puts a community on a path of development whose consequences are not fully manifest in the short term of 1 or 2 years. Lobao (1990) observed that some impacts were manifest a decade later. As noted earlier, counties with greater industrialized farming in 1970 had a significantly poorer well-being a decade later: These counties had a lower median family income, higher family poverty rates, and higher income inequality relative to other counties and net of past county conditions. For the heartland states, economists at the Federal Reserve Board of Kansas City (Drabenstott and Smith, 1996, p. 4) indicate that differences in communities will widen over time. According to these economists, industrialized agriculture will have two effects on rural communities. Industrial agriculture production and processing will cluster in some communities resulting in an increase in jobs and income. The economic links between industrial agriculture and communities, however, will be different than they were under commodity production because more production inputs are purchased from nonlocal sources, and more of the profits go to nonlocal owners of the firm.

Types of Studies Conducted on the Effects of Industrialized Farming: Research Designs and Methodology

Analysts have used primarily four different types of research designs to assess whether industrialized farms have detrimental impacts on communities. Each design has inherent strengths and limitations in being able to comprehensively analyze industrialized farming and its many potential impacts. (The author has outlined the strengths and limitations that are intrinsic to each research design. An individual study will vary as to how the analysts have exploited the strengths or overcome the limitations of the design.)

Case-study designs provide indepth analysis of the consequences of industrialized farming in a single or multicommunity site. Usually, a comparative case-study design is implemented whereby a community or communities characterized by industrialized farming are contrasted with a community or communities with a different farming pattern (usually moderate-sized, family owned and operated farms). A comparative case-study design allows communities to be matched on similar background characteristics, such as location near cities and dependency on farming as an economic base, which helps to 'control' (or exclude) extraneous factors that influence the relationship between farming type and community well-being.

Macrosocial accounting designs involve statistical analysis of secondary or precollected data from government and other sources, such as the Census of Agriculture and Census of Population, to document relationships found in regional social structure (MacCannell, 1988). Community units, such as counties and townships, and states are the research focus. To assess the consequences of industrialized farming, analysts usually compare its effects relative to other farming (usually smaller or moderate-sized family farm units) and over time, while controlling for other, nonfarm factors known to affect community well-being. Multivariate statistical techniques, such as regression procedures and discriminant analysis, are used so that the effects of farm structure are assessed net of other community conditions.

Regional economic impact models use linear programming methods to estimate impacts on employment and income for regions, states, and smaller units such as counties and cities. These studies focus on the integration of business enterprises in markets and use programs, such as variants of input–output analysis, to model the backward and forward linkages with enterprises in other industries and to estimate resulting local impacts. The costs and benefits of varying different firm-level practices can be estimated.

Survey-design studies use samples of populations from any number of communities. These studies use interviews or questionnaires to document how industrialized farming affects residents or a particular social group exposed to industrialized farming as compared with those who are not (such as those residing in family farming communities). In contrast to macrosocial accounting and economic impact models which are based usually on secondary or precollected data, the researchers using a survey design collect primary data directly from individuals or families. Multivariate statistical procedures such as regression are used to assess the consequences of farm variables net of other community and individual characteristics.

Conclusions of Studies Examining Industrialized Farming and Community Well-Being

As noted, to assess the consequences of industrialized farming, it is useful to examine the body of past work conducted by researchers from various social science disciplines, over time, and using different methodologies. This analysis is built upon a metaanalysis by Lobao (1990), who examined research from 1930 to 1988. A metaanalysis is a quantitative assessment across individual studies that allows for comparison and integration of empirical findings (Cooper, 1989). Metaanalyses are useful for drawing systematic conclusions when many empirical studies by different researchers exist that examine the same research question. To develop the pool of empirical studies used in the analysis, the literature from 1988 to the present was surveyed. (This table has been updated from Lobao (2000) by adding all empirical studies published on the topic in *Rural Sociology* (the major scholarly journal in this field) since 2000. A review of reviews in the *American Journal of Agricultural Economics* (the major scholarly journal in this field) over the past 5 years was undertaken but no empirical studies were found on the topic. In addition, the following journals were surveyed for reviews relevant to the topic: *Agriculture, Food and Human Values, Culture and Agriculture, Sociologia Ruralis, Southern Rural Sociology, American Journal of Alternative Agriculture* (now the *Renewable Agriculture and Food Systems* journal), *Journal of Rural Studies* and the *International Journal of the Sociology of Agriculture and Food*. Two scholarly search engines – *Google Scholar* and *Agricola* were also used to find relevant reviews. Some reviews were located serendipitously. The programs and abstracts for the 2000–05 Annual Meetings of the Rural Sociological Society also were reviewed.) **Table 1** shows the classification of findings by research design of 56 studies conducted since the 1930s on the effects of industrialized farming on community well-being. In most studies (all of the sociological studies), the authors hypothesize that where farms are of larger- scale or industrialized in terms of organizational characteristics, they have a detrimental impact on the indicator(s) of community well-being, relative to family owned and operated farms. These relationships are expected to be found across communities and over time.

Types of Detrimental Impacts Reviewed by Social Scientists

Social scientists review that industrialized farms are related to relatively worse conditions for the following community impacts:

Socioeconomic Well-Being

- Lower relative incomes for certain segments of the community: Greater income inequality (income polarization between the affluent and the poor) or greater poverty (Tetreau, 1940; Goldschmidt, 1978a; Heady and Sonka, 1974; Rodefeld, 1974; Flora *et al.*, 1977; Wheelock, 1979; Lobao, 1990; Crowley, 1999; Deller, 2003; Crowley and Roscigno, 2004; Peters, 2002; Lyson and Welsh, 2005; Durrenberg and Thu, 1996).
- Higher unemployment rates (Skees and Swanson, 1988; Lyson and Welsh, 2005).
- Lower total community employment generated (Marousek, 1979; Thompson and Haskins, 1998).

Social Fabric

- Population: Decline in local population size where family farms are replaced by industrialized farms; smaller population sustained by industrialized farms relative to family farms (Goldschmidt, 1978a; Heady and Sonka, 1974; Rodefeld, 1974; Wheelock, 1979; Swanson, 1980).
- Class composition: Social class structure becomes poorer (increases in hired labor) (Gilles and Dalecki, 1988; Goldschmidt, 1978a; Harris and Gilbert, 1982).
- Social disruption:
  - increases in crime rates and civil suits NCRCRD (1999);
  - general increase in social conflict (Seipel *et al.*, 1999);
  - greater childbearing among teenagers (Lobao, 1990);
  - increased stress, social-psychological problems (Martinson *et al.*, 1976; Schiffman *et al.*, 1998);
  - swine CAFOs located in census blocks with high poverty and minority populations (Wilson *et al.*, 2002);
  - deterioration of relationships between hog farmers and neighbors (Jackson-Smith and Gillespie, 2005; McMillan and Schulman, 2003); and
  - more stressful, less neighborly relations (Constance and Tuinstra, 2005; Smithers *et al.*, 2004).
- Civic participation: deterioration in community organizations, less involvement in social life (Goldschmidt, 1978a; Heffernan and Lasley, 1978; Poole, 1981; Rodefeld, 1974; Lyson *et al.*, 2001; Smithers, 2004).
- Quality of local governance: less democratic political decision-making, public becomes less involved as outside agribusiness interests increase control over local decision-making (Tetreau, 1940; Rodefeld, 1974; Goldschmidt, 1978a; McMillan and Schulman, 2003).
- Community services: fewer or poorer quality public services, fewer churches (Tetreau, 1940; Fujimoto, 1977; Goldschmidt, 1978a; Swanson, 1980).
- Retail trade: Decreased retail trade and fewer, less diverse retail firms (Goldschmidt, 1978a; Heady and Sonka, 1974; Rodefeld, 1974; Fujimoto, 1977; Marousek, 1979; Swanson, 1980; Skees and Swanson, 1988; Foltz *et al.*, 2002; Foltz and Zueli, 2005, Smithers, 2004; Gomez and Zhang, 2000).
- Reduced enjoyment of property: Deterioration of landscape, odor in communities with hog CAFOs (Schiffman *et al.*, 1998; Wing and Wolf, 1999, 2000; Constance and Tuinstra, 2005; Reisner *et al.*, 2004; Wright *et al.*, 2001; Kleiner, 2003; McMillan and Schulman, 2003).
- Health: neighbors of hog CAFOs review upper respiratory, digestive tract disorder, eye problems (Wing and Wolf, 1999, 2000; Constance and Tuinstra, 2005; Reisner *et al.*, 2004; Wright *et al.*, 2001; Kleiner, 2003).
- Real estate values: residences closest to hog CAFOs experience declining values relative to those more distant

NCRCRD, 1999, p.46; Seipel *et al.*, 1998; Constance and Tuinstra, 2005; Reisner *et al.*, 2004; Wright *et al.*, 2001).

Environment

- Ecosystem strains: depletion of water, other energy resources (Tetreau, 1940; Buttel and Larson, 1979; NCRCRD, 1999).
- Environmental consequences of CAFOs: increase in Safe Drinking Water Act violations, air quality problems, and increased risks of nutrient overload in soils (NCRCRD, 1999).

The studies indicate the types of community conditions associated with industrialized farming. To what extent do the studies overall provide evidence of detrimental impacts? With regard to the public policy interest in the topic, a count of studies where any detrimental impacts were found was conducted. The studies were classified according to whether the researchers review: Largely detrimental impacts; mixed findings (i.e., researchers review only some detrimental impacts were found); and no detrimental effects. Classifying the studies is somewhat complex because each may test a number of relationships about industrialized farming. The studies were placed into detrimental/no detrimental outcome categories based on whether the findings for the majority of relationships tested consistently fell into either of these two categories. Remaining studies are those in which the researchers found some detrimental impacts but other relationships were mixed, as described further below.

Out of the total 56 studies, researchers review largely detrimental impacts in 32, some detrimental impacts in 14, and no evidence of detrimental impacts in 10. Thus, 82% (46 out of 56) of the studies review finding some negative impacts of industrialized farming. This analysis provides quantitative evidence of the consistency in past research which has led to the working hypothesis that industrialized farming jeopardizes community well-being.

Of the 32 studies where social scientists found predominantly detrimental impacts, the following points should be noted. First, these studies use the four major types of research designs described earlier, comparative case study, macrosocial accounting, regional economic impact models and surveys. Studies reviewing detrimental impacts exist across all time periods and regions of the country. These studies review adverse outcomes for socioeconomic well-being, social fabric, and environmental conditions, using both scale and organizational measures of industrialized farming. In sum, the studies provide a great deal of evidence, produced over many years by researchers using different research designs, on the negative impacts of industrialized farming.

Of the 14 studies where social scientists review some, but not consistently negative impacts of industrialized farming, the following points should be noted. These studies provide mixed findings, in that though adverse effects on some community indicators were found, at least one of the following also occurred: Industrialized farming had no statistical relationship with other indicators (i.e., there was an absence of any relationship); industrialized farming had a trade-off effect, with beneficial effects on certain indicators; industrialized farming did not consistently produce negative impacts for all time periods or regions; or industrialized farming produced beneficial effects for some groups but detrimental to other groups. Mixed findings are evident to a greater degree in regional economic impact and macrosocial accounting studies (**Table 1**).

Regional impact studies tend to show costs–benefits for economic performance indicators, with larger farms injecting greater total income into the community, but also producing less employment relative to smaller farms (e.g., Heady and Sonka, 1974; Marousek, 1979). Macrosocial accounting studies often test a number of relationships, adding to the greater potential of mixed findings. Lobao's (1990) study is an example. For counties in the 48 contiguous states, industrialized farming had no relationship with poverty and median family income at either of the two single time points (1970 and 1980); however, industrialized farming was related to higher income inequality at both time points and also to lower family income, higher poverty, and higher income inequality over the 1970–80 decade (i.e., counties with greater industrialized farming in 1970 experienced relative declines in socioeconomic well-being over the decade).

Other research designs also provide examples of mixed findings. An example of a case study showing mixed effects is Wright *et al.* (2001) conducted in six counties with CAFOs in Minnesota. This study found that CAFOs had positive effects for farmers who expanded their operations; detrimental effects for neighbors to CAFOs whose ability to enjoy their property deteriorate; detrimental effects for younger and midsized producers unable to expand because expansion by others had restricted their access to markets; and no effects for those who were not neighbors or who were not expanding. A survey (Jackson-Smith and Gillespie, 2005) also found mixed effects for the impacts of large-scale, hired–labor–dependent dairies on community social relations. Farm size was the strongest predictor of neighbors' complaints about dairy operations, but demographic attributes of dairy farm owners had a greater affect on their relationships with neighbors than did farm size or use of hired labor.

The 10 studies that found no detrimental impacts of industrialized farming used mainly macrosocial accounting designs and tended to analyze only indicators of socioeconomic well-being. Lobao's and Schulman's (1991) study is an example. They examined whether industrialized farming was related to higher family poverty across agricultural regions in the US for the period 1970–80. They found no significant relationship in any of the four regions analyzed. Finally, a recent survey design study (Foltz and Zueli, 2005) found no evidence that large farms are unlikely to purchase locally once the presence of local suppliers was taken into consideration. Instead, they demonstrated that purchasing patterns are commodity specific and determined by community attachment, and local supply considerations.

Summary and Conclusion

Social scientists often debate whether empirical research should be oriented around disciplines' accumulated body of

knowledge or, conversely, address the public interest and provide critical knowledge to build civil society (Burawoy 2005). Social science research on industrialized farming accomplishes both objectives. This study addresses the long-standing question, does industrialized farming jeopardize the well-being of communities, through systematically evaluating the findings of studies from the 1930s to the present. On the basis of a sample of 56 studies, 82% provide evidence of adverse impacts (57% reviewing largely detrimental effects and 25% some detrimental effects). These impacts were reviewed in studies using various research designs and across different time periods and regions.

The types of community impacts reviewed by social scientists were detailed earlier and are seen in the following general relationships. For socioeconomic well-being, researchers noted that industrialized farming was related to higher income inequality and to lower community employment, relative to moderate-sized family farming. Higher income inequality indicates that industrialized farming is less likely to sustain middle-class communities. Places with higher income inequality also are prone to other social problems because the gap between the affluent and the poor is greater. With regard to other socioeconomic impacts, such as total income injected into the community, regional economic impact models were likely to review beneficial impacts. The findings for income inequality, however, suggest that income growth is impeded in trickling down to families.

Studies assessing consequences for the social fabric of communities were likely to find detrimental impacts. Industrialized farming affects the social fabric of communities through altering population size and social composition which affect crime, social conflict, family stability, the local class structure, community participation, and local shopping patterns. Case studies reviewed the loss of local autonomy, in which communities become increasingly subject to the influence of external business owners, whose interests may not be compatible with their own. More recent studies reviewed environment impacts. As large animal confinement operations house densely concentrated livestock, they are prone to a host of negative environmental impacts on water, air, and human health.

Given the relative consistency of past research, four sets of impacts of industrialized farming for farming-dependent communities in Heartland states can be anticipated: Impacts on socioeconomic well-being, social fabric, the environment, and regional imbalances. Communities that receive industrialized farming are likely to increase population relative to other communities (i.e., if local family farmers are not displaced). These communities may increase employment and per capita income, but as shown by the NCRCRD (1999) study, this may not be at a rate significantly different from comparison locales. Communities with industrialized farms are likely to experience greater income inequality; government services for the poor and other disadvantaged groups are likely to be needed in these locales. Communities that gain new industrialized farming will encounter stresses in the social fabric; community decision-making is likely to be more subject to corporate farm interests; and in the case of large livestock confinement operations, communities will be at risk for environmental and health problems, entailing the need for state and local government intervention. Communities that lose moderate-sized family farms, in part because of transaction cost advantages (e.g., volume buying–selling) and public incentives given to industrialized farms, will lose a base of middle class producers and experience rifts in social fabric, including population decline. These communities are likely to have declines in other businesses and in the local property tax base and may require government aid for social and public services.

Not discussed in this review are alternative economic development strategies that farming-dependent communities can pursue. Notwithstanding arguments that vertical integration into farming and production contracts are the only options left to keep American farmers farming, there are alternatives and some working examples are discussed in NCRCRD (1999). Deller (2003) suggested that if the results of their analyses held true for other time periods, then policies aimed at preserving family farms in the name of economic growth might be misplaced. Instead, policy should be aimed at the promotion of alternative sources of income for farm families.

During the time frame in which previous studies have been conducted, Welsh (2009) notes that the structure of agriculture has changed dramatically toward a bimodal distribution of large and small farms each operating in different market structures. He recommends that new studies examining the relationship between agriculture and community should examine the impacts of changed market structure as well as how public policies can mitigate the negative impacts of agricultural industrialization.

From a sociological standpoint, government plays a role in the types of consequences that industrialized farming will have for community well-being. It establishes the legal–institutional framework for regulating these farms. It establishes the incentive structure offered to agribusiness firms in their location decisions. It provides the public services needed to mop up the destabilizing impacts of industrialized farming, such as a rising crime rate, increased social conflict, and the need for social services to cope with a changing population. Moreover, government will need to provide the social services related to population decline and poverty alleviation in communities which lose family farming. (In nonfarm-dependent communities, government intervenes in a number of ways when paid employment, such as in manufacturing and mining declines: through programs such as unemployment insurance, various income transfers, such as welfare payments, for which independent farm operators are generally not eligible due to property ownership; through retraining programs, such as for workers who lose jobs because of North American Free Tree Agreement; and through enforcement of community rights in plant closure laws. Owing to their farming base, farm-dependent communities usually cannot make as full use of these social safety nets as can other communities.)

The role that laws regulating corporate farms have in countering detrimental community impacts of industrialized farming had only been alluded to by some researchers. Lobao and Schulman (1991, p. 596) postulated that one of the reasons why a few studies have found that industrialized farming has had less adverse effects in the North Central Heartland Region (relative to the South and West) is due to its agrarian history of protection of family farming and regulation of corporate farming. NCRCRD (1999) also indicated that 'relatively lax anticorporate farming laws, weak environmental regulations and permissive groundwater access laws' not surprisingly encouraged large, animal confinement operation to locate in Kansas.

The role that corporate farming laws play in protecting rural communities has been alluded to in past research NCRCRD (1999) but only recently addressed by Lyson and Welsh (2005). When they examined states with anticorporate farming laws (Iowa, Kansas, Minnesota, Missouri, North Dakota, South Dakota, Oklahoma, and Wisconsin), they found that agriculture-dependent counties in states with such laws fare better on economic measures, that is, less families in poverty, lower unemployment, and higher percentages of farms realizing cash gains. In the comparison of states with less restrictive versus states with more restrictive laws, they generally found the same results as with the comparison of states with anticorporate farming laws and states without such laws. Additional research is needed to explain these findings, such as whether corporate farming laws *per se* or broader aspects of the institutional regulatory environment are protecting the fortunes of local communities.

It is clear, however, that within states, remote communities distant from metropolitan centers particularly need state-level protection. Remote rural counties appear to be targeted as recent operating sites by large animal confinement operations. Research by Wilson *et al.* (2002) demonstrated that census blocks in Mississippi with high percentages of African Americans or people in poverty were much more likely to be the locations of swine CAFOs. Of all local governments, remote rural counties have the least resources (staff, economic development, and social service budget) to cope with industrialized farming. They are in weak positions to bargain successfully with external corporations, to regulate their operations once they are in place, and to protect community social life and environment overall. State protection from industrialized farming is most critical in remote communities due, in part, to the fragility of local government (Lobao and Kraybill, 2005). From a social science standpoint, the farming system in place today has been created from both market forces and government policy and programs. It is thus logical that government can also be an instrument in transforming this system toward greater public accountability.

Integrated Pest Management in Tree Fruit Crops

JF Brunner, Washington State University, Wenatchee, WA, USA

© 2014 Elsevier Inc. All rights reserved.

Glossary

Active ingredient A chemical or chemicals in a pesticide formulation that kills, repels or otherwise provides control of a pest.

Degree-day A degree-day is the heat experienced by an organism when the temperature is one degree more than the lower development threshold for 24 h. Degree-days are a measure of heat units or physiological time. Insect development rate is driven by physiological time, degree-days, and not chronological time.

Ecology The science of the relationships between organisms and their environments.

Invasive pest An invasive pest, or exotic pest, is a species that has been introduced to an area where it is not native. Invasive pests often cause serious problems in the region where they are introduced because their populations are not suppressed by natural factors that limit them in their native home.

Molecular marker (genetic marker) A fragment of DNA sequence associated with part of the genome. Molecular markers are used to identify a particular sequence of DNA.

Natural enemy An organism that utilizes another organism as a food source. Natural enemies of insect pests (herbivores) are predators, parasites, pathogens, and nematodes.

Pesticide A substance used for controlling pests or other organisms harmful to plants or animals.

Phenology The study of relationships between cyclical or seasonal biological processes and climate, such as insect development.

Pheromone A chemical produced and released by an animal, which influences the behavior or development in other members of the same species.

Treatment threshold The number of pests that triggers a control action preventing a level of damage that would exceed the cost of the control action.

Introduction

Integrated Pest Management (IPM) was born in the late 1950s primarily out of a crisis in agriculture from the overuse of synthetic pesticides and an increasing concern over the ecological consequences of these pest-control tools. Rachel Carson's, 1962 book 'Silent Spring' highlighted ecological concerns over synthetic pesticides. Stern *et al.* (1959) articulated the philosophy of IPM, which was further developed by Geier and Clark (1961). Two books, Entomology and Pest Management (Pedigo, 1989) and Introduction to Insect Pest Management (Metcalf and Luckmann, 1982), and an annual review of entomology article (Kogan, 1998) are recommended as resources introducing the principles and examples of IPM from an arthropod perspective. The purpose of this article is to briefly introduce basic concepts of IPM with an emphasis on IPM of arthropods in perennial crops, and a specific examination of the outcome of more than 40 years of research and implementation on apple in Washington State.

IPM is an approach that applies the principles of ecology, especially population biology, to the management of pests in agricultural, forest, or urban environments. There are many definitions of IPM, but the one proposed by Rabb (1972) that "pest management is the intelligent selection and use of pest-control actions that will ensure favorable economic, ecological, and sociological consequences," captures the basic elements used in most definitions. The simple image of a structure can help show how the elements of IPM work together (**Figure 1**). An IPM program is built on a foundation that includes the knowledge of pest and natural enemy biology, their correct identification, and ecology. Intervention against a pest should be based on the risk of crop injury and is only taken if the pest's population exceeds a level where the cost of preventing injury exceeds the cost of the intervention. Therefore, sampling to estimate the pest's population level is required. Control actions are not implemented unless the pest's population exceeds a specified level, a treatment threshold. Phenology models are valuable tools that make sampling activities more efficient and the implementation of tactics more effective. IPM does not rely on a single tactic but utilizes multiple tactics to mitigate the negative impacts of pests. Tactics are used in an integrated approach with the goal of limiting or relegating the use of tools that disrupt natural controls to options of last resort.

General Principles of Integrated Pest Management

Identification

The correct identification of pests and their natural enemies is core to an IPM program. Although many pests of agriculture are well known, there are challenges associated with the accurate identification of some organisms. Plant pathogens like fungi, bacteria, and viruses can represent a special challenge for identification. For example, fungal diseases of apple expressed as rots in storage seemed to be well established until Dr. C. L. Xiao looked more closely. He found two fungi, one a new species and the other an expansion of the geographic distribution of the fungus, that had been misidentified and not previously recognized as problems (Xiao *et al.*, 2004, 2005). Some insects, such as parasitic wasps and temperate fruit flies in the genus *Rhagoletis*, are difficult to identify because external appearance of individuals within these groups are so similar.

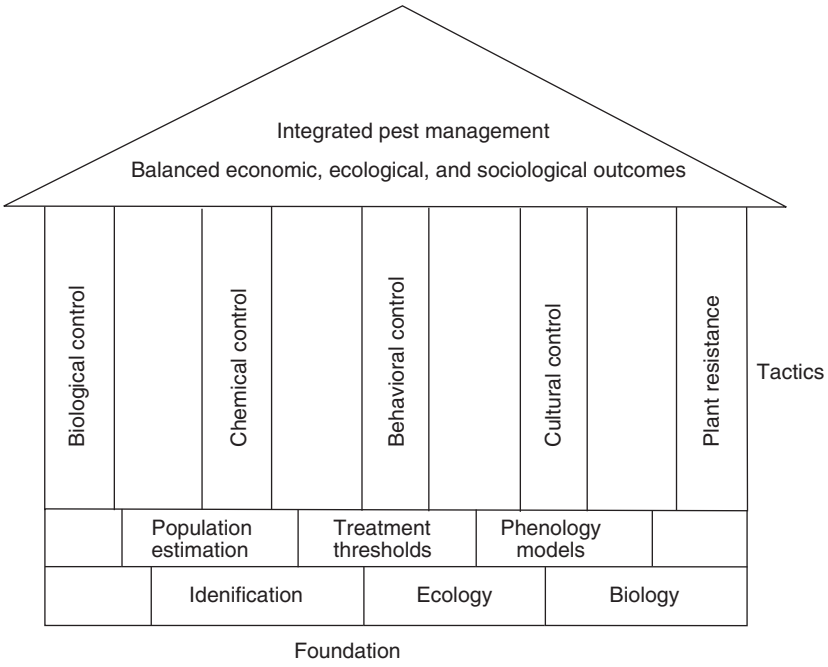

Figure 1 Representation of an Integrated Pest Management (IPM) system built on a foundation of sound biological understanding and tools that inform the integrated use of tactics.

The use of molecular techniques has helped with the identification of many disease organisms as well as species of insects that are morphologically identical.

Example of Identification:

Important pests of grapes grown in California are two species of leafhoppers: *Erythroneura elegantula* Osborn and *Erythroneura variabilis* Bearmer. A small parasitic wasp identified as *Anagrus epos* Girault attacked the eggs of these leafhoppers. This parasitoid was found to overwinter successfully in wild blackberry (*Rubus* spp.) on an alternative leafhopper host, *Dikrella cruentata* (Gillette), and the closer the association of blackberry patches to grape plantings, the higher the potential for biological control of leafhoppers in grapes (Doutt and Nakata, 1973). A similar association has been reported between prune trees that support an alternative leafhopper host, *Edwardsiana prunicola* (Edwards), of *A. epos* (Murphy *et al.*, 1996). However, in 1998, Triapitsyn reported that parasites previously identified as *A. epos* were actually a composite of three species in the genus *Aegagrus* Halliday, including a new species he identified (Triapitsyn, 1998). The importance of this new information will help researchers to sort out which species of *Anagrus* are using alternative overwintering leafhopper hosts and to better characterize and manage alternate hosts in and around commercial grape plantings that will enhance biological control of pest species.

Biology

Understanding the biology of pests and their natural enemies is the key to IPM. Without information on life cycle and seasonal development, it is impossible to effectively implement tactics to limit pests or conserve natural enemies. Being able to predict when a pest is present, and in which life stage, is also fundamental to the implementation of IPM. The life history of a pest usually follows a similar annual pattern, especially in temperate production zones, but because the rate of pest development is governed by environmental conditions, that is, by physiological time and not chronological time, the temporal occurrence of life stages can vary considerably from year to year.

Insect Ecology, Population Biology, and Sampling

Insect IPM is built on the concepts of ecology and it is, therefore, valuable for anyone desiring to understand the principles of IPM to become familiar with insect ecology. A good general resource on insect ecology is Peter Price's (1997) book by the same name. Following an introduction, this book deals with trophic relationships, populations, communities, and distributions. IPM deals with managing populations of pests and natural enemies so an understanding of population biology is especially important.

The largest population of an organism that can be supported on a crop over time is referred to as the carrying capacity. Insect populations are seldom observed at a carrying capacity in natural systems, like forests, and, of course, cannot be tolerated in managed systems like agriculture. It is most common for the population of a pest insect to be limited, by the plant itself (e.g., nutritional quality and resistance mechanisms), by their own interactions (competition – over utilizing the plant resource), or by actions of other organisms (predators, parasites, and pathogens) that use pests as food.

Pest populations can be impacted by factors that are density dependent or density independent. Density-independent factors

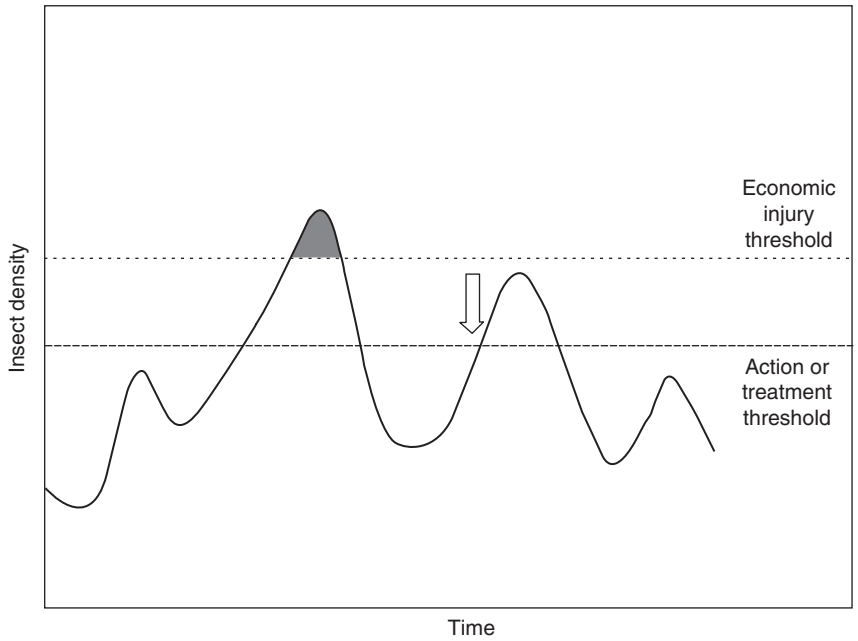

Figure 2 The economic injury level is the pest density above which crop loss equals the cost of taking a control action. The treatment or action threshold is the pest density at which a control is applied (arrow) to prevent the pest's population from exceeding the economic injury level.

are those that impact a proportion of the pest's population regardless of its size. Weather (freezes, droughts, etc.) or catastrophic events like fires are examples of density-independent factors that can impact a pest's population. In agriculture, the most useful density-independent factors are pesticides. When pesticides are applied, they kill a fixed proportion of the pest's population. Although pesticides are powerful tools in managing pest populations, they, and other density-independent factors, do not exert a regulatory impact on populations. Density-dependent factors are those that increase or decrease in response to the pest's population. Natural enemies of insects are examples of density-dependent factors. Their populations track changes in their prey or host. In many cases, density-dependent factors can regulate the population of a pest below levels, economic injury thresholds, that cause crop injury.

Knowing the level of a pest or natural enemy population is a core principle of IPM. This information is required to make decisions on the need to apply control tactics and to assess the effectiveness of those actions. As it is not possible to obtain an absolute measure of a pest or natural enemy population, sampling (monitoring) activities that estimate the level of a pest's population is fundamental to an effective IPM program. There are various means of estimating populations of organisms, which are outlined in *Ecological Methods* (Southwood and Henderson, 2000).

Economic Injury and Action Thresholds

All pests of agricultural crops cause some impact to the crop plant or product of that crop, but these effects are negligible until pest populations exceed a certain level. In IPM, this level is referred to as the economic injury level, which is defined as the pest population that causes crop loss equal to the cost of control. Conceptually, the relationship between the pest density, economic injury level, and action (treatment) threshold is shown in Figure 2.

For many diseases of agricultural crops, there is an assumption (sometimes incorrect) that the pathogen is always present. When the pathogen is present, all that are needed for the organism to cause levels of disease that exceed an economic injury level are environmental conditions conducive to rapid disease development and spread. For such plant pathogens, it is very difficult, if not impossible, to use a measure of inoculum levels before the application of control measures. Therefore, in most cases treatment thresholds for these pathogens are determined and controls applied when environmental conditions favorable for the pathogen are present. An example of this is the disease apple scab, *Venturia inaequalis* (Cke.) Wint. Controls are applied for this disease on the basis of a model driven by environmental factors of temperature and duration of leaf wetting (MacHardy and Gadoury, 1989).

For most insect pests, there is a population level, that is, the action or treatment threshold, where a control must be applied so that the economic injury level is not exceeded. While the concept of an economic injury level is helpful, in reality, its implementation is challenging because the value of a crop is seldom known, especially for high-value specialty crops, at the time a pest control decision is made. If the economic value of the crop is not known, then determining the level of injury that would equal the cost of control cannot be known. In addition, the impact on fruit or nut crops of pests that attack the foliage, such as spider mites or aphids, can be difficult to assess because resource reservoirs in the tree compensate for, and thus can delay, the effects of these pests for a year or more (Welter *et al.*, 1984).

Phenology and Degree-Day Models

Phenology is the study of relationships between environmental conditions and biological processes such as insect development. Phenology or degree-day models are used in IPM to predict the seasonal occurrence of plant pathogens and arthropod pests. These models associate environmental conditions with the development of pest. For insects, degree-days are used as a measurement of heat units or physiological time. A degree-day is the heat experienced by the insect when the temperature is one degree more than the lower threshold for 24 h.

The upper and lower temperature thresholds are usually determined by laboratory studies where an insect is reared at different constant temperatures. Lower and upper thresholds are estimated from the development rate data as shown in Figure 3. Development thresholds differ for each insect and often for each stage in an insect's life cycle. A fixed number of degree-days are required to complete each life stage. Once development thresholds are known, this information can be used to calculate physiological time, or degree-days, using simple formulas that utilize daily maximum and minimum temperature information (Baskerville and Emin, 1969).

Access to environmental data in or near agricultural plantings is important in predicting disease development and the life cycle of insects. A more specific discussion of degree-day models and their implementation in an online decision support system occurs later in this article.

Tactics

Chemical Control

Chemical controls (pesticides) are often the dominant tactic used in IPM programs. Chemical controls are designed to reduce pest (insect, pathogen, rodent, etc.) populations below levels that will not negatively impact the crop. Before the development of synthetic insecticides, which occurred after World War II, pesticides included horticultural oils, lead arsenate, soaps, lime sulfur, nicotine, and a few other inorganic elements like sulfur and copper. The modern pesticide era began with the discovery of chemicals like dichlorodiphenyltrichloroethylene and organophosphate (OP) insecticides that had high efficacy against insects. Their dramatic effect against pests of agriculture resulted in their overuse leading to a crisis that eventually resulted in an alternative approach, the development of IPM. IPM viewed chemical controls as one tool integrated into an overall strategy to mitigate the negative impacts of pests on a crop. Because of the high and often immediate impact of chemical controls on a pest population, their appropriate place in an IPM program was as a last resort in a multitactic approach.

The regulation of pesticides through the US Environmental Protection Agency (EPA) has changed the availability of chemical controls over the past two decades. The US federal Food Quality Protection Act (FQPA) of 1996 required the EPA to review and reregister all pesticides on the basis of risk. In addition, all uses of a pesticide were considered in determining risk, not just agricultural uses. This represented a significant shift from the previous regulatory approach, which balanced risks and benefits of pesticides. The highest priority for the reregistration of pesticides under FQPA was the OP insecticide class. Specialty crops were one of the biggest users of this insecticide class, so they were especially impacted by FQPA. Progress of EPA toward the implementation of FQPA can be found on their web site.

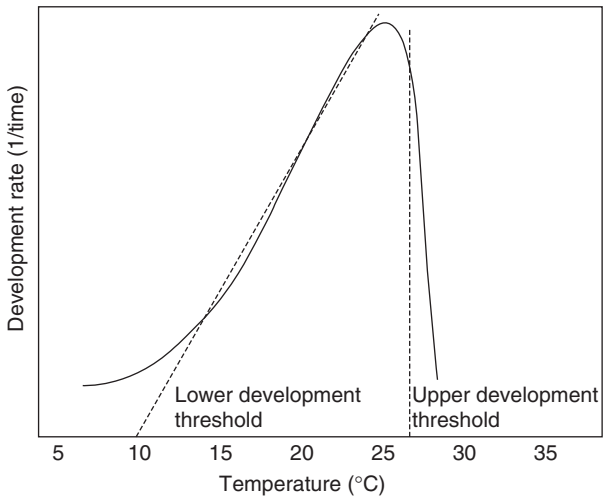

Figure 3 The rate of insect development increases as temperatures; they are exposed to increase, up to a point where development is suppressed, the upper development threshold. An estimate of the lower development threshold is established by extending a straight line through the ascending development curve to the temperature access.

Biological Control

In natural ecosystems, populations of different organisms are regulated by many different factors, including biological ones. Plant populations are regulated by herbivores, natural enemies regulate herbivore populations, and natural enemies of herbivores are regulated by their own natural enemies. In agricultural systems, herbivores (arthropods, fungi, and bacteria) are considered pests. Natural enemies that attack pests provide what is called biological control. Natural enemies of insects include predators, parasitoids, pathogens, and nematodes.

Examples of biological control of insect pests fall into three categories: classical, augmentation, and conservation. When a pest is introduced into a new location, its populations can increase rapidly due to a lack of natural controls that most often do not accompany the introduction. Classical biological control involves finding and introducing one or more natural enemy of the new invasive pest from its country of origin. After establishment, the introduced natural enemy can often provide complete or partial biological control of the invasive pest. Augmentation biological control occurs when a natural enemy of a pest is reared and released or moved from one place where it occurs to another where it is absent. This method of biological control is used most commonly in greenhouse environments for control of pests like spider mites and whiteflies. Conservation biological control occurs by following

management practices that preserve already existing populations of natural enemies. This is the most common form of biological control practiced in perennial cropping systems like tree fruit.

A core principle of IPM is that biological control can often keep pest populations below levels that would result in crop losses. For many pests, biological control will occur if the natural enemies are conserved, that is, they are not disrupted. In high-value crops like tree fruits, biological control has its primary value against pests that attack the foliage, such as aphids and spider mites. To establish and sustain biological control in these crops, IPM strives to use insecticides as a tactic of last resort or to use those that are known to have minimal impact on natural enemies.

Behavioral Controls

Insects communicate in a number of different ways, for example, visually, through sounds, and chemically. Pheromones are used as communication cues between individuals of the same species. Ants use trail pheromones to help other members of the colony get from their nest to a food source and return to the nest again in an efficient manner. Alarm pheromones are used by aphids to warn other aphids that a predator is on the prowl. Aggregation pheromones attract individuals of the same species to locations for purposes of feeding and mating. Sex pheromones are produced and released by one sex to attract the opposite sex for purposes of mating. Sex pheromones are highly species specific, making them potential tools for monitoring and controlling pests.

Adolph Butenandt and colleagues identified the chemical structure of the first sex pheromone in 1959 from the silk worm, *Bombyx mori* L. (Butenandt *et al.*, 1959). Sex pheromones may be a single compound or a blend of several compounds each in a specific ratio that optimize attraction. Soon after the discovery of moth sex pheromones, it was suggested that these chemicals might be useful as tools to control pests in managed systems like agriculture (Gaston *et al.*, 1967). The use of sex pheromones as a form of pest control has been referred to as mating disruption because the mechanism of control was associated with the disruption of male orientation to the female, thus preventing or disrupting the mating process (Cardé, 1990; Cardé and Minks, 1995).

Once the chemical structure of a sex pheromone was identified, they were synthesized in the laboratory. Synthetic pheromones are chemically identical to those produced by the insect and are highly attractive. When placed in lures, these synthetic sex pheromones attract males of the same species to traps where they can be captured and counted as a means of estimating the population of the species. However, the most important use of sex pheromones has been their use as controls for many key pests of forest and agricultural crops.

When sex pheromones are placed into dispensers that release them over a long period of time (several months), the normal behavior of the targeted pest is disrupted and mating is prevented, suppressed, or delayed. The release rate of pheromone coming from dispensers varies but is always many times higher than the amount of pheromone released by the insect. For example, the codling moth female releases approximately 6.5 ng h^{-1}, whereas a single pheromone dispenser releases approximately 1000 times that amount or approximately 50 mg ha^{-1} h^{-1} (Witzgall *et al.*, 2008). Because sex pheromones only impact one insect species, they are an excellent selective control for pests.

Pheromones have been used to control several pests in forests, vegetable, and perennial crops. More than 660 000 ha are treated with pheromones as controls for codling moth in pome fruit (apple and pear); Oriental fruit moth, *Grapholita molesta* (Busck), in stone fruit (peach and nectarine); European grapevine moth, *Lobesia botrana* (Denis & Schiffermuller); European grape berry moth, *Eupoecilia ambiguella* (Hübner), in grapes; pink bollworm, *Pectinophora gossypiella* (Saunders), in cotton; leafroller (Tortricidae) species in tea and other crops; and the Gypsy moth, *Lymantria dispar* (Linnaeus), in deciduous forests (Witzgall *et al.*, 2008). Witzgall *et al.* (2008) provide a review of the chemical ecology and management of codling moth. A specific case for the successful use of codling moth sex pheromones in apple IPM in Washington State is discussed later in this article.

Plant Resistance – Genetics

Plants have natural defenses against organisms that attack them, for example, herbivores and pathogens. Painter (1951) broadly classified plant resistance to insects into three categories: nonpreference, antibiosis, and tolerance. Nonpreference refers to factors in a plant that make them unattractive to pests. Antibiosis refers to factors in a plant that adversely affect pest development or mortality. Tolerance refers to plants that have an ability to overcome or compensate for injury inflicted by pests. Plants grown for food are often selected for traits that enhance yields and quality, often at the expense of factors that protect the plant from attack by pests.

Naturally occurring pest resistance factors can sometimes be found and utilized. A classic example of plant resistance to a pest that helped to save the French wine industry involved the grape phylloxera, *Daktulosphaira vitifoliae* (Fitch), a root-feeding insect. The grape phylloxera was accidentally introduced into Europe in the late 1800s. French wine grape plants were highly susceptible to this pest and it threatened to ruin the entire industry. American grapes were known to be resistant to the grape phylloxera and by grafting American grape roots onto French wine varieties the problem was solved.

Understanding the genetics of crop plants can help plant breeders incorporate desired traits of resistance into crop. Perennial crops like apple represent a particular challenge for breeders because of the long time required to grow trees and evaluate fruit for desired qualities. At Washington State University (WSU), the apple breeding program has expedited the process by utilizing rootstocks that result in apple trees bearing within 2 years. Even so it takes a minimum 15 years to find an apple variety good enough for consideration as a commercial variety, and then it takes several additional years to plant enough trees to generate sufficient production to gain a significant share of the market. As more is known about the apple genome, breeders are using modern molecular methods, like genetic markers for resistance to diseases (Stankiewicz *et al.*,

2002), to screen seedlings from parental crosses and discard those that do not carry the desired genes for resistance. As more becomes known about the location of genes and their role in apple, it will be possible for breeders to identify parents that carry genes for pest resistance and incorporate these traits with those for high yield, fruit quality, and other horticultural attributes.

Cultural Control or Ecological Management

Cultural control or ecological management refers to practices that modify the agricultural environment in ways that favor the crop's health relative to that of the pest. The concept involves finding weak links in the pest's life history that can be exploited. In annual cropping systems, cultural control can take the form of changing planting dates such that the seasonal life cycle of a pest is avoided or by crop rotations that reduce the buildup of a pest population in the same location on the same crop. Sanitation is another management practice that can be used to reduce a pest's population by eliminating overwintering habitats. In dry land wheat production, the practice of alternating a year of wheat with a year of summer fallow can help reduce certain pests while conserving water. Trap cropping is another possible cultural practice that can be used to attract a pest away from the primary crop. Trap crops can also be treated with an insecticide to reduce the pest's population without having to treat the primary crop.

There are fewer options for implementing cultural controls in perennial crops as annual strategies like those cited above are not readily available or possible. It is possible to manage plant nutrition to reduce vegetative growth that favors insect pests like aphids or pear psylla. However, this approach is a difficult balance between practices that make the tree less favorable for pests and the need to enhance fruit size and quality. Sanitation is useful for pests like the shothole borer, which colonizes pruned wood left in an orchard or piled up near the orchard border (Doerr *et al.*, 2008). A cultural practice designed to enhance or conserve biological control in orchards is the establishment of plants in or near the orchard, which provides alternative prey or hosts for natural enemies. In apple, the establishment of wild rose and strawberry gardens has been used to enhance biological control of leafrollers.

Example of Cultural Control:

The discovery of a small parasitic wasp, *Colpoclypeus florus* (Walker), in Washington (Brunner, 1996) prompted studies on the biology of this natural enemy. *Colpoclypeus florus* originally was brought from Europe to Canada and released in hope that it would provide biological control of leafrollers in forests or agricultural crops. This parasitoid was found to need large leafroller larvae in order to overwinter, but the leafroller species that are pests of orchards in Washington overwinter as small larvae that are unsuitable as hosts for *C. florus*. An alternative host, the strawberry leafroller, *Ancylis comptana* Frölich, turned out to provide a good overwintering host for *C. florus*, but this leafroller only occurred on wild rose in riparian habitats at some distance from most apple orchards (Pfannenstiel *et al.*, 2010; Unruh *et al.*, 2012). Dr. Tom Unruh, USDA-ARS scientist, found that by planting gardens of wild rose and commercial strawberries near orchards, he could provide an overwintering site for *C. florus* and enhance the levels of parasitism of leafroller larvae in the orchard. Many Washington growers have established and maintained these overwintering refuges for *C. florus* as a means of conserving this important natural enemy.

Integrated Pest Management in Tree Fruit with Focus on Apple as Example

Unique Challenges and Opportunities of Perennial Cropping Systems

Annual crops can take advantage of their transitory nature to manage pests, like crop rotation or planting dates, but because they are annually disturbed systems, it is more difficult to accumulate and sustain components in the crop environment that would stabilize IPM programs. By contrast, there are opportunities in high-value perennial crops to manage the crop environment and reduce long-term impacts of pests. For instance, conserving natural enemies of pests in an orchard provides stable biological control of several insect or mite pests, thus reducing the need to intervene with insecticides.

Perennial high-value crops, like tree and small fruits, citrus, nut crops, and grapes, have specific challenges and opportunities to the implementation of IPM programs. Challenges are tied to the high value of the product and the high expectation of quality, both external (cosmetic) and internal. The high value of the fruit results in a low tolerance for losses due to pests. The consequence of a low pest tolerance is too often the overuse of crop protection technologies, primarily pesticides.

Side Bar Example:

Modern high-density apple orchards (2500 or more trees ha^{-1}) in Washington State can produce a yield of 70 000 kg ha^{-1}. The cost of growing, harvesting, storing, packing, and marketing these apples varies by variety, but costs are high, approximately \$30 000 ha^{-1}. Not all apples harvested are packed and sold, primarily due to high demands for fruit quality; however, growers are usually able to market 80% of their harvested crop. If the net return to the grower were \$0.13 kg^{-1}, then, based on production of 70 000 kg ha^{-1}, net return to the grower would be approximately \$10 200 ha^{-1}. If a pest increases crop loss by 0.5%, the grower's profit would be reduced by roughly \$200 ha^{-1}. The cost of an additional pesticide to prevent this level of crop loss would be approximately \$125 ha^{-1}. In this scenario, there is little incentive for a grower to take the risk of crop loss by not applying a pesticide. The challenge for IPM is to develop tools that assess the risk of a pest causing crop loss that allows the grower to make informed decisions about applying a pesticide. If the pesticide is needed on the basis of the level of the pest's population, then the investment pays off by increasing grower profit by \$75 ha^{-1}. If the pesticide is not needed but the grower treats anyway, profit is reduced by approximately \$200 ha^{-1}.

According to the US Department of Agriculture, National Agricultural Statistics Service (USDA-NASS) report, Noncitrus

Fruits and Nuts 2012 Preliminary Summary, there are 1.84 million ha of tree fruit in the US. Different tree fruit crops are produced in different regions and therefore face different challenges when implementing IPM programs. The eastern US faces more problems with diseases compared with the western US because of a wetter and more humid climate. In addition, several key insect pests occur in the eastern US, which are not present in the west.

The key pest in an agricultural production system is that organism, or small number or organisms, for which most controls are directed to prevent crop loss. For tree fruit crops, key insect pests are direct pests, those that feed on the fruit. A direct pest can cause high levels of crop loss if management practices are not used to reduce its population (see Key pest example). Key pests for different tree fruit crops are listed in Table 1 (Figure 4).

Key Pest Example:

The codling moth, *Cydia pomonella* (Linnaeus), is the key pest of apple in the western US. The adults lay eggs on or near the apple. On emergence from the egg, the small caterpillar bores through the skin of the apple. It then moves toward the apple core, where it consumes the seeds. A codling moth population can increase rapidly from low levels where less than 0.2% of the crop is affected to where, in just two generations or one growing season, up to 25% of the crop can be injured. If uncontrolled for longer periods, the codling moth will destroy up to 80% of the crop each year. Based on USDA-NASS pesticide-use survey information, roughly 50% of insecticides applied to apple in Washington is used for control of codling moth.

Table 1 Key insect and disease pests of different tree fruit crops

Tree fruit crop	*Key insect pest*	*Key disease pest*
Apple	Codling moth (W)	Apple scab (E)
	Apple Maggot (E)	Powdery mildew (W)
	Plum Curculio (E)	
Cherry	Cherry fruit fly (E,W)	Brown rot (E)
	Plum curculio (E)	Powdery mildew (W)
Pear	Pear psylla (E,W)	Fire blight (E,W)
Peach, Nectarine	Oriental fruit moth (E,W)	Brown rot (E)
Plum	Plum curculio (E)	Brown rot (E)

Abbrevations: E, Eastern US; W, Western US.

Apple Integrated Pest Management in Washington

The remainder of this article will focus on apple IPM in Washington and specifically deal with arthropod pests. This approach will allow for a more detailed inspection of specific examples of apple IPM programs and the changes that have occurred over several decades and will address specific concerns that threaten to undo advances made in IPM programs over the past five decades. Although limiting discussion to the specifics of apple IPM in Washington narrows the focus, many of the principles addressed are relevant to tree fruit and other perennial cropping systems in the US and around the world.

The best resource describing the arthropod pest complex attacking tree fruit in Washington is the book Orchard Pest Management (Beers *et al.*, 1993), which is available online with updated articles. The key arthropod pest in Washington apple production is the codling moth. If not controlled, even a small codling moth population can result in crop loss that is economically unacceptable to a grower. Because tolerance of codling moth is low, there is little opportunity to rely on biological control (predators, parasites, or diseases) as a primary tactic. In addition to the codling moth, there are several other pests that directly attack apple fruit. These include

Figure 4 Image of codling moth adult and fruit injury. Photo of (a) a codling moth adult and (b) an apple cut open to show a codling moth larva and the feeding damage it causes.

leafrollers, thrips, scales, and true bugs like stink bugs and the mullein plant bug. While this latter group of pests can cause severe crop loss, they tend to be localized geographically and their impacts are not the same on all apple varieties.

Another group of arthropods (aphids, leafhopper, leafminer, and spider mites) are referred to as indirect pests because they do not directly attack apple fruit, rather they feed on foliage, bark, or roots. Often referred to as secondary pests they indirectly impact fruit quantity or quality when their populations become too high. Because higher populations of indirect pests can be tolerated in orchard compared with direct pests, there is a greater potential that biological control can be more effective. Apple IPM strives to conserve natural enemies of these pests by implementing selective chemical control programs.

Integrated Mite Control

The introduction of synthetic insecticides and miticides into the tree fruit production systems in the 1950s resulted in outstanding control of pests. Initially, control was so good that one or two applications of an insecticide provided control of all pests for an entire growing season. However, this phenomenon was short lived. Some insects and spider mites soon developed resistance to the miracle pest-control products, resulting in the need for more frequent applications and the use of higher rates.

Example of Resistance — Pesticide Treadmill:

Pests develop resistance when they are exposed to pesticides that eliminate most of their population. Some of the individuals in the population have a genetic predisposition to tolerate the effects of the pesticide. Therefore, these individuals survive in higher numbers than those that are susceptible to the pesticide. As pesticide use continues, those individuals that survive make up a higher and higher proportion of the pest's population, which then reduces the efficacy of the pesticide in suppressing the pest. Eventually, higher concentrations of the pesticide are needed to keep the pest population below levels that will cause crop loss; however, the battle is eventually lost as resistance to the pesticide continues to increase. Often, the strategy to rescue a crop from a pest that has developed resistance to a pesticide is to switch to a pesticide with a different mode of action, that is, a different mechanism of killing the pest. Although this approach can work for a while, there are individuals in the population that are less susceptible to the new pesticide. These individuals survive and eventually more frequent use and higher concentrations of the new pesticide are required to protect the crop. This cycle can be repeated over and over again and is referred to as the pesticide treadmill.

The pesticide treadmill scenario (see example of resistance) was played out in Washington apple orchards in the 1960s. Spider mites increased as a problem because they had developed resistance to synthetic insecticides used to control the key pest, codling moth, and there were no natural enemies of spider mites surviving in orchards. Apple growers were forced to use miticides, specific chemicals that control spider mites. However, the spider mites soon developed resistance to these products. The situation was in crisis mode; growers were using multiple miticide applications per year, but spider mite populations were still high enough in many orchards that apple foliage a turned brownish color in late summer.

Dr. Stan Hoyt, WSU entomologist, discovered that the use of low rates of certain OP insecticides provided control of the codling moth but at the same time allowed populations of the western predatory mite (WPM), *Galendromus occidentalis* (Nesbitt), to survive in the orchard (Hoyt, 1969). After a year or two of implementing Dr. Hoyt's discovery, the predatory mite suppressed spider mite populations to nondamaging levels. This program became known as integrated mite control because it integrated two tactics, chemical and biological control, and brought about a stable IPM program (**Figure 5**).

A key reason why his program was successful was that the WPM developed a tolerance to certain OP insecticides and could, therefore, survive in the orchard, even when these products were used for control of other pests. Integrated mite control is an example of an IPM program born out of crisis. It occurred because of the careful observations and research of an outstanding scientist and the willingness of a tree fruit industry to trust the results of sound science and adopt a new way of doing things. The economic value of integrated mite control to the Washington apple industry is in the millions of dollars. For example, most of the apple acres in the US use miticides to provide suppression of spider mites. The National Agriculture Statistics Service surveys of pesticide use in apple over the past 20 years show that Washington growers apply a miticide to an average of 24% of apple acres. By comparison, the average percentage of apple acres treated with miticides in Michigan and New York are 76% and 70%, respectively. If integrated mite control saved Washington apple growers a half of one miticide treatment annually, the savings would be about $7.5 million, or more than $300 million over the past four decades.

Figure 5 Photo of the western predatory mite (WPM) feeding on a pest, the European red mite. Image provided by Dr. E.H. Beers, Professor of Entomology, Washington State University.

The development of integrated mite control in Washington attracted the interest of other regions in the US and around the world as a model for integrating chemical and biological controls in orchard and other production systems. In eastern apple orchards, the integration of chemical and biological control of spider mites looked different from Washington because the natural enemies adapted to that climate were different. In Pennsylvania, growers adopted the use of low rates of OP insecticides and applied them to every other row. This approach protected a small predacious beetle, *Stethorus punctum* (LeConte), that fed on spider mites (Asquith and Hull, 1979). In recent years, however, a predaceous mite, *Typhlodromus pyri* (Scheuten), has become more common in Pennsylvania orchards and is more effective than *S. punctum*. In Michigan, a predatory mite, *Neoseiulus* (=*Amblyseius*) *fallacis* (Garman), was also shown to provide suppression of spider mites when combined with selective pesticides and orchard ground cover management (Croft and McGroarty, 1977). In other parts of the world with climates similar to Washington, the WPM was imported and established in orchards, thus replicating integrated mite control that mirrored in many respects that of apple production in Washington.

In the OP era, two additional apple pests were controlled biologically, namely the western tentiform leafminer, *Phyllonorycter elmaella* Doganlar & Mutuura, and white apple leafhopper, *Typhlocyba pomaria* McAtee. The leafminer developed resistance to OP insecticides and became a serious pest of apple in the mid-1980s. Research showed that a small parasitic wasp, *Pnigalio flavipes* (Ashmead), was present in orchards that did not use certain OP insecticides, namely chlorpyrifos and methyl parathion. When these two OPs were removed from the apple pest-control program, *P. flavipes* provided biological control of the leafminer, even when other OP insecticides were used in orchards. Like the WPM, *P. flavipes* was able to survive in apple orchards because it had developed a tolerance to azinphos-methyl. During the same time period, and as apple growers implemented the use of pheromones for codling moth control, a small parasitic wasp, *A. epos*, became more common in orchards. This parasitoid attacks the egg of the white apple leafhopper and after 3–5 years of programs that reduced the use of OP insecticides, populations of the leafhopper were reduced to levels that did not require additional insecticide intervention.

Pheromone Technology

It was nearly 20 years after the sex pheromone of the codling moth had been identified (Roelofs *et al.*, 1971) that the first product, Isomate®-C, was registered as a control for codling moth in the US. Early research demonstrated the value of pheromones (mating disruption) as a control for codling moth in Washington apple orchards; however, that research also revealed that if initial codling moth populations were too high, then pheromones alone were not sufficient to provided adequate crop protection (Gut and Brunner, 1998). In addition to not being a stand-alone control for high codling moth populations, pheromones were also considered to perform better when the area treated was large, that is, 8 ha or more, and the shape of the treated area was not long and narrow.

In 1995, the USDA provided funding for a codling moth area-wide management project (CAMP). The goal of the project was to demonstrate the value of pheromones using an area-wide approach. The project's objectives were to demonstrate that pheromones would provide control of codling moth, reduce the amount of insecticides applied for codling moth control by 70%, and improve biological control of secondary pests. Five CAMP sites were established: three in Washington, one in Oregon, and one in California (Calkins and Faust, 2003; Brunner *et al.*, 2002). All of the CAMP sites were successful in meeting the objectives of the project.

The Howard Flat CAMP site was a predominantly apple growing area located near Chelan, Washington. Howard Flat was approximately 480 ha of mostly contiguous apple plantings, but with a few plantings of cherry and pear. There were 36 growers operating orchards at Howard Flat, who took their fruit to four different warehouses where fruit were stored, packed, and marketed. In addition, there were 16 crop consultants, who assisted growers in making horticultural and pest management decisions.

An advisory committee was established of key growers and crop consultants to work with CAMP personnel at Howard Flat. This group met weekly during the growing season for the first 3 years of the project, then less frequently over the past 2 years. Information collected by CAMP personnel was distributed to all growers and was posted on a large board near the Howard Flat site, where all growers could access the information. Before the start of CAMP, data were obtained from crop consultants on codling moth captures in pheromone trap and growers provided spray records and information on fruit injury caused by codling moth in 1994. These baseline data showed that growers applied an average of 2.7 insecticides for codling moth control and there was an average of 0.9% fruit injury by codling moth. In addition, an average of 33 codling moths was captured in pheromone traps over the 1994 growing season. Together, these data indicated that apple production at Howard Flat was dealing with relatively high populations of codling moth (**Figure 6**).

At the start of CAMP, hand-applied pheromone dispensers were the only products available for codling moth mating disruption. These dispensers cost approximately \$250 ha^{-1} plus another \$38–63 ha^{-1} for application costs. The cost of the mating disruption treatments was subsidized by \$125 ha^{-1} for the first 3 years of the project to encourage growers to participate. In the past 2 years, growers were required to pay the full cost of the mating disruption treatments. In the first year of the Howard Flat CAMP, all but two growers agreed to participate. In the final 4 years, all growers participated in the project.

CAMP personnel monitored codling moth and leafrollers in all orchards to maintain a consistent assessment of the seasonal activity and relative densities of these pests. For codling moth, pheromone traps were used at a rate of 1 ha^{-1}. Lures (10X) used in traps had ten times the normal amount of codling moth pheromone in order to make them more attractive in orchards treated with high levels of pheromone. Traps were checked weekly and lures changed as needed. CAMP personnel assessed crop injury in most orchards every year just before harvest. Crop consultants made recommendations to growers on pesticides needed to control pests,

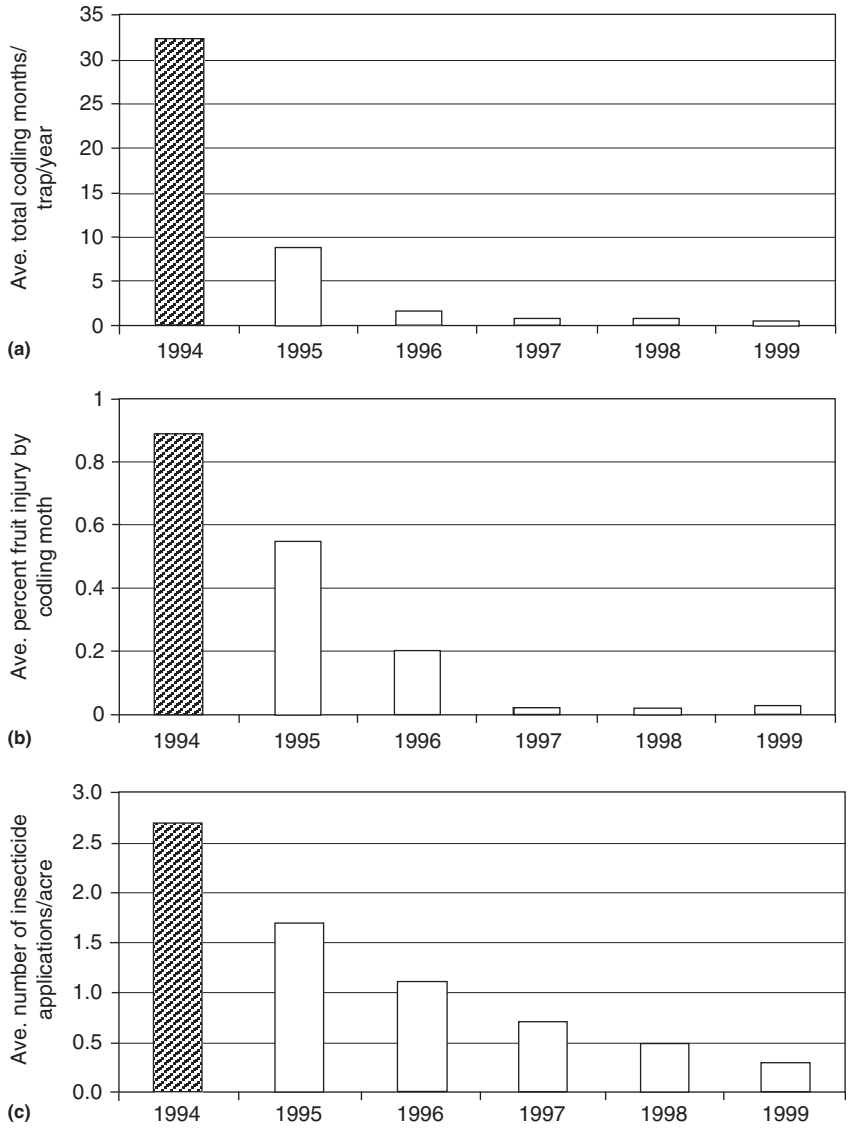

Figure 6 Results from the codling moth area-wide management project (CAMP) at Howard Flat, WA; (a) average capture of codling moth per trap per year, (b) average percentage fruit injury each year, and (c) the average number of supplemental (in addition to pheromone treatments) insecticides applied to control codling moth each year.

including insecticide applications as needed for codling moth to supplement the mating disruption treatments.

In the first year of the Howard Flat CAMP, the average number of codling moth adults captured in traps declined from 33 to 10 per trap. This decline was not unexpected because the use of mating disruption products is known to suppress capture of male moths in traps. However, in years 2–5, the average number of codling moths captured per trap continued to decline and in the past 3 years of the project, most traps (80–90%) captured no moths for the entire season (Figure 6). These data are evidence that the codling moth populations had declined substantially in the first 2 years of the project.

The percentage fruit injury after the first year averaged 0.55%, down from the preproject level of 0.9%. The number of insecticides applied for codling moth, as a supplement to mating disruption treatments, averaged 1.7 ha^{-1}, down from the preproject average of 2.7 ha^{-1}. After the second year of the project, fruit injury had declined to an average of 0.2% and the number of supplemental insecticides to an average of 1.1 ha^{-1} (Figure 6). In years 3–5, the percentage fruit injury varied between 0.01% and 0.03%. The number of supplemental insecticides applied for codling moth control also continued to decline, and by the last year of the project, the average number of applications was 0.3 ha^{-1}. Most growers did not apply any insecticides to supplement the control of codling moth provided by mating disruption in this year (Figure 6). Based on the preproject data at Howard Flat, insecticide use targeting control of codling moth was reduced by 85%, exceeding the project goal of 70%.

The CAMP at Howard Flat, and two other locations in Washington that showed similar results, demonstrated to

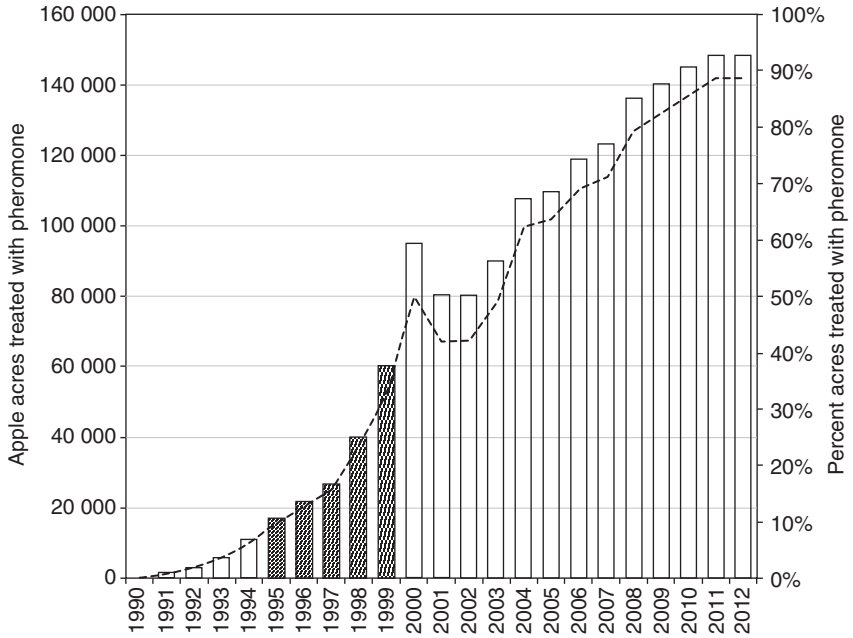

Figure 7 The number of apple acres treated with codling moth mating disruption products (pheromones) and percentage of bearing apple acres treated.

apple growers that codling moth mating disruption was a powerful selective control for their key pest. Although pheromone technology was more expensive than the use of insecticides alone, its added value by reducing fruit injury and eventually reducing the need for supplemental insecticide treatments convinced many growers that it was a good investment. The method of actively involving the grower and crop-consulting community in the planning and execution of the project at Howard Flat is an excellent example of how to extend a new technology into an agricultural system. As a result of CAMP, the adoption of codling moth mating disruption grew dramatically as growers learned about the success of the project. The percentage of bearing apple production area in Washington treated with pheromone technology for control of codling moth continued to increase after CAMP. In 2012, nearly 90% of bearing apple production area was treated with mating disruption products for the control of codling moth (Figure 7).

Phenology Models and Decision Aid Systems

Models that predict the development of a disease or arthropod pest are valuable tools in IPM programs. The Predictive Extension Timing Estimator, developed at Michigan State University, represented an early effort to automate the delivery of pest models (Welch *et al.*, 1978; Brunner *et al.*, 1980). In Washington State, the development of the WSU Agriculture Weather Network (AWN) made automation of model delivery a possibility. AWN maintains and provides accesses to environmental data from more than 132 stations throughout the state. A team led by Dr. Vince Jones from WSU developed the Decision Aid System (WSU-DAS). This web-based system currently delivers information on 10 insect, 4 disease, and 2 horticultural models (Jones *et al.*, 2009).

The power and utility of WSU-DAS comes through the integration of phenology model output with management recommendations and links to a WSU database of pesticides recommended for control of tree fruit pests. This automated delivery system allows users to create a personal profile where they specify the weather stations and models they wish to access. When the user logs onto WSU-DAS, only the weather stations and models they are interested in appear. The user can add weather stations and/or models to their personal account at anytime.

A screen-capture example of WSU-DAS output for the codling moth model is shown in Figure 8. In this example, the current conditions of codling moth development are shown along with appropriate management recommendations. A powerful feature of WSU-DAS is the capacity to predict pest phenology from 1 to 10 days by using temperature data derived from NOAA forecasts. Information on pest phenology can be viewed in different graphical formats or as a table. WSU-DAS also allows growers a choice of filters that automatically restrict pesticide options to those that fit different kinds of programs like organic or no-OP.

The WSU-DAS represents a state-of-the-art technology for delivering critical information in real time to assist growers and crop consultants in making pest management decisions. It represents the kind of decision support system that Washington tree fruit growers and crop consultants have said they want more of. WSU-DAS is now available to users through their smart phone or tablet.

WSU-DAS also provides an important link to other WSU online educational materials. For example, the front page of the WSU-DAS has a series of temporally relevant short stories that allows the user to access more information on the subject if desired. There are more than 120 such stories that automatically appear at appropriate times during the growing

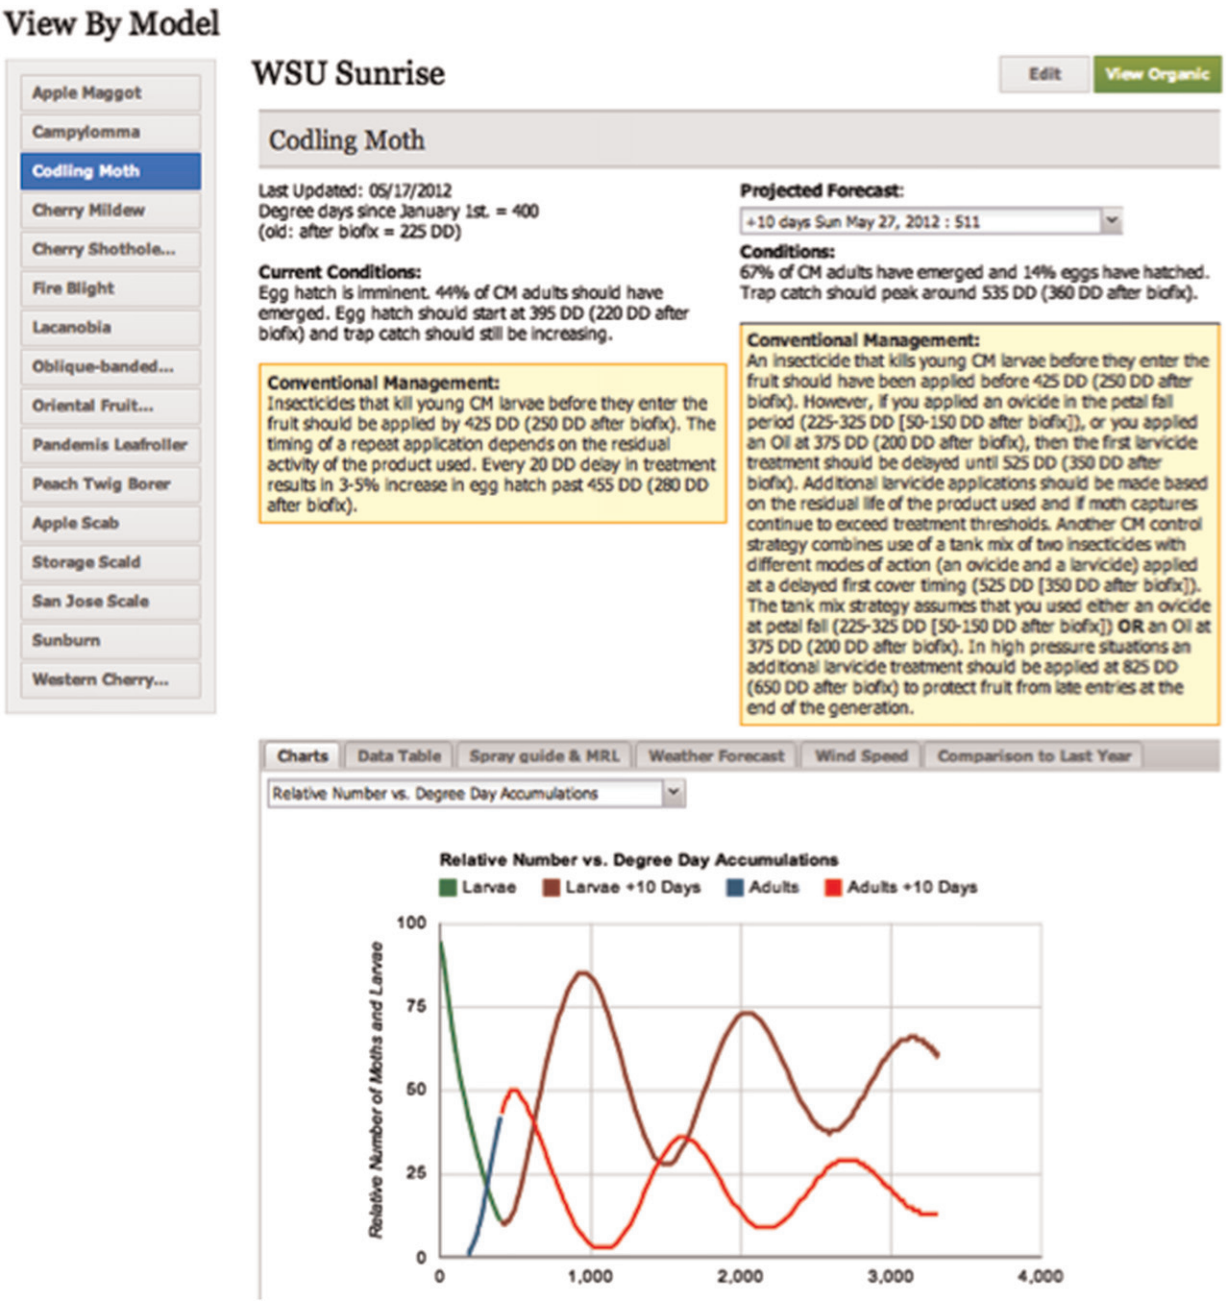

Figure 8 Screen capture of the codling moth model output from the Washington State University-Decision Aid System (WSU-DAS) showing current and forecast phenology and management recommendations.

season, thus leading users to important information about pests or horticultural practices.

Apple Integrated Pest Management Transition Project

In 2006, the EPA announced a decision to phase out, over 5 years, the use of the OP insecticide azinphos-methyl (AZM) from most agricultural uses. AZM had been the most used insecticide for codling moth control in Washington apple production for more than 40 years and was also important for control of other pests in tree fruit production throughout the US (Jones *et al.*, 2010). In response to this regulatory action, WSU implemented a 4-year Pest Management Transition Project (PMTP). Funding for this project was provided initially by the Washington state legislature, then later by Washington State Department of Agriculture through Specialty Crop Block Grants. The private pesticide industry had been in the process of developing and registering alternatives to OP insecticides and, through research, WSU had developed a good understanding of how these OP-alternatives fit apple IPM programs (Doerr *et al.*, 2012). The emphasis of PMTP was on

education: How to use OP-alternatives in apple IPM so that growers and crop consultants would not experience failures in their crop protection programs.

The primary education vehicles used in PMTP were Implementation Units (IU), which were made up of a small number (10–15) of growers and crop consultants. The IUs met four to five times in the first 2 years of the project. At these meetings, participants were given the PMTP handbook, which was used as a guide and knowledge source about OP-alternatives and how they best fit into an apple IPM program. The PMTP handbook is available online in both English and Spanish. The IU participants represented approximately 50% of the bearing apple production area in Washington, so the influence of information transfer from these groups was significant.

Additional ways of distributing information on OP-alternatives was through the project's web site, e-newletters, workshops, field days, winter grower meetings, and popular press articles. The PMTP employed an assessment and documentation specialist to assist with surveys and to interface with nonagricultural and farm worker communities. PMTP conducted surveys of crop consultants in 2007 and 2009 and of apple growers in 2008 and 2010. Information from these surveys allowed the project to assess perceptions and practices and changes over time.

Survey results pointed out concerns of both growers and crop consultants. For example, in the first survey, both crop consultants and growers (97.5% and 92.5%, respectively) agreed or strongly agreed that the cost of codling moth control would increase due to the phaseout of AZM, and these concerns changed little in the second survey (90.9% and 93.3%). Crop consultants were more confident that WSU had developed good information on alternatives to AZM in first and follow-up survey (82.5% and 84.0%) than were growers (65.6% and 66.1%), most likely because crop consultants were more in tune to changes in pest control products coming onto the market, and they participated more actively in meetings where research on new products was presented. Between the first and second surveys, growers indicated that their use of OP insecticides decreased by 9%, whereas crop consultants said that their recommendations for use of OP insecticides decreased by 40%. In addition to the comprehensive mail surveys, PMTP also conducted online surveys of IU participants and implemented use of the Turning Point™ audience response system as a means of gathering information from audiences at various meetings. Results of all these surveys along with questions asked can be found on the PMTP web site.

Outreach to the farm worker community, primarily Hispanic workers, provided important information on the safety of OP-alternative products being used in apple orchards. The project produced a poster, which has been used by growers, orchard managers, and pesticide applicators to explain the relative safety of OP-alternatives and why workers are allowed to reenter an orchard sooner than when OP insecticides were used.

Enhancing Biological Control

Biological control has been a key component of apple IPM since the establishment of integrated mite control in the late 1960s. When changes are made in practices in any cropping system, there is always a possibility that they will cause changes in IPM programs, positive or negative. When the use of OP-alternatives was implemented in apple IPM, prevailing thinking was that because these products were safer to humans and wild life, and were more selective in their control of pests than previous pesticides, they would also have little impact on natural enemies of pests. In part, this expectation was based on the way insecticides are typically screened for their impact on natural enemies, that is, by assessing acute mortality against the adult stage. Soon after the OP-alternatives were registered and used on a significant number of hectares in Washington, and other areas around the world, reports began to surface about the disruption of biological control of spider mites and aphids.

A multistate, multiinstitution research project funded through the USDA-National Institute for Food and Agriculture (NIFA) Specialty Crop Research Initiative program, Enhancing Biological Control in Western Orchards (EBCWO), had as one of its objectives examining the effects of selected OP-alternatives on a group of natural enemies found in tree fruit and walnut orchards. The project discovered that although OP-alternatives had little or no impact on adults of natural enemies, some showed significant sublethal effects, that is, the reproductive ability of the natural enemies was significantly impacted. These findings reveal why screening for acute toxicity of adult natural enemies alone does not reveal the true negative impacts of many OP-alternatives, and for that matter other pesticides. For more information on this project's findings on pesticide effects on natural enemies, and other information generated by the project, readers are directed to refer to the web site.

Another way EBCWO project is helping to enhance biological control in orchards is through the development of new monitoring methods and phenology models for natural enemies. Natural enemies are often very difficult to sample. Their presence is usually lower than that of pests and many are active at night. The EBCWO project has shown that different combinations of traps (color and shape) and lures (herbivore-induced plant volatiles) can attract different kinds of natural enemies. Some of the lure–trap combinations are highly selective, primarily capturing only one or two natural enemy species. Use of these new monitoring tools makes the presence of natural enemies in orchards much more apparent. In addition, they can be used to show the impact of IPM practices, such as the use of a toxic pesticide, on the abundance of a natural enemy.

In general, the phenology of natural enemies in orchards is not well understood. By using the natural enemy-monitoring tools developed by the EBCWO project, detailed information on the seasonal abundance of some natural enemies has become available. These data are being used to develop phenology models of these natural enemies. Once validated, the natural enemy models will be incorporated into WSU-DAS so that growers and crop consultants will know when natural enemies are present in the orchard and therefore when to avoid use of pesticides that would be most detrimental to their populations. New knowledge on the effects of OP-alternative on natural enemies, phenology models that predict when natural enemies will be present, and new monitoring tools that would confirm their presence or their absence are all

contributions that will help Washington growers conserve the free services provided by biological control in their orchards.

Impact of Integrated Pest Management on Use of Insecticides in Apple

NASS has conducted national surveys every other year starting in 1991 on pesticide use in tree fruit crops. These data include the percentage area treated, average number of applications, the pounds of active ingredient of each pesticide used and the total pounds of active ingredient used on each tree fruit crop in each state. The active ingredient is the chemical in a formulated pesticide that is responsible for control of the targeted organism.

Tree fruit crops are often reported as having the highest pounds of insecticide active ingredient applied per unit area relative to other agricultural crops. A primary reason for this is that tree fruit crops use horticultural mineral oil (HMO), which is classified as an insecticide in NASS surveys. HMO makes up the highest proportion of pounds of active ingredient of insecticides applied to tree fruit crops. This is due to the way the active ingredient for HMO is calculated. NASS assigns eight pounds of active ingredient to each gallon of HMO applied. HMO is typically used before bloom in tree fruit crops control of overwintering eggs of the European red mite and aphids, as well as various scales, most notably the San Jose scale. In most tree fruit crops, HMO is applied only once per season, and not all orchards are treated. Although some HMO is used in summer, the amount used is much lower than in the prebloom period.

In Washington, HMO (plus from 1999 on kaolin, a clay product used for sunburn but registered as an insecticide) made up an average of 83% of the total pounds of active ingredient of insecticides applied to apple (range 77% in 1995 and 1997–92% in 2011). Of all other insecticides used on apple in Washington, the OP insecticides made up an average of 51% (range 62% in 1995 and 41% in 2009) of the total pounds of active ingredient between 1991 and 2011. The active ingredient of OP insecticides applied averaged 4.48 kg ha^{-1} pounds between 1991 and 2011, but there was a significant decrease over this period. For example, between 1991 and 1997, the active ingredient of OP insecticides averaged 6.8 kg ha^{-1}, whereas the average between 2007 and 2011 was 2.2 kg ha^{-1}.

The amount of active ingredient in different insecticide formulations varies considerably. For example, 1.8 kg ha^{-1} of AZM active ingredient is applied when using the high label rate, whereas only 0.33 kg ha^{-1} of chlorantraniliprole (Altacor®) active ingredient, an OP-alternative insecticide, is applied when using the high label rate. Thus, comparing pounds of active ingredient of a pesticide makes it difficult to capture changes in the number of applications of different kinds of pesticides used over time. By calculating an area application, it is easier to follow the change in the average number of applications of all or different kinds of pesticides over time. An area application does not take into account the weight of active ingredient. It can be calculated from the NASS data by multiplying the average number of applications ha^{-1} by the proportion of ha treated. For example, if an insecticide is applied 2 times to 40% of an area

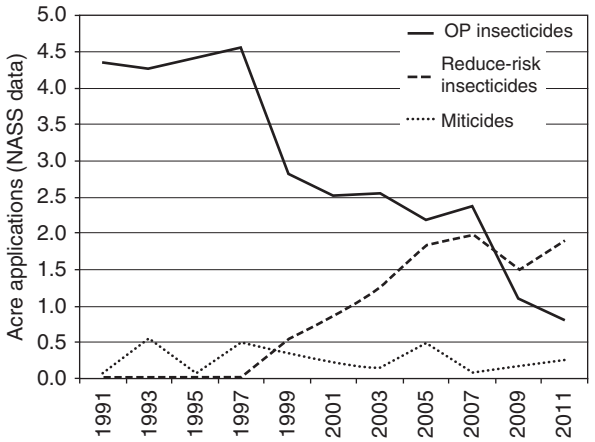

Figure 9 The acre applications of organophosphate (OP), OP-alternatives, and miticides used on apple in Washington State between 1991 and 2011 based on data from National Agricultural Statistics Service (NASS) surveys.

(acre or hectare), the number of area applications is 0.8 (2.0 × 0.4 = 0.8). By using area application values, HMO and kaolin data can be included in an assessment, because the number of times they are applied per area does not skew the information in the same way it does if the weight of active ingredient is used. The average number of area applications between 1991 and 2011 for all insecticides, including pheromones, HMO, and kaolin, was 8.1 (range of 10.8 in 1993 to 6.8 in 2001).

Figure 9 shows the number of area applications of OP and OP-alternative insecticides, miticides, and pheromones in Washington apple between 1991 and 2011. The drop in the area applications of OP insecticides between 1995 and 1999 is partially due to regulatory action restricting use of certain OP products during the growing season but can also be attributed to the adoption of mating disruption for control of codling moth. The area applications of OP insecticides remain relatively constant at approximately 2.5 until 2007, just after the EPA made the decision to phase out AZM. The dramatic drop in area applications of OP insecticides in 2009, and again in 2011, was due to apple growers shifting their programs to OP-alternatives. While regulatory action no doubt influenced the shift from OP to OP-alternative insecticides, the PMTP helped growers and crop consultants make the transition with minimal difficulty. The use of miticides in Washington apple orchards has remained relatively stable over time, with an average of 0.26 area applications between 1991and 2011. The increase in area applications of pheromones is attributed to the value apple growers saw in this selective control for their key pest.

New Threats to Integrated Pest Management

All IPM programs are subject to continual change as government regulations limit use of practices or technologies, especially pesticides, and as new technologies are developed to manage pests. A change that can result in an immediate and profound impact on an IPM program is the introduction of a new pest from a foreign country. One approach in dealing with a foreign pest is to find and introduce natural enemies from the pest's land of origin. This classical biological control approach

can at times provide sufficient suppression of the invasive pest so that additional controls are not required. However, even if such an approach is successful, it typically takes several years to find, culture, and then introduce natural enemies and, in most cases, the level of biological control is only partially successful and chemical controls are often still required.

The discovery of the brown marmorated stink bug (BMSB), *Halyomorpha halys* (Stål), in Pennsylvania signaled the establishment of what has become a very serious pest of tree fruit crops and many other agricultural crops (Hoebeck and Carter, 2003). The BMSB has more than 300 reported host plants including all tree fruit crops. It can, therefore, move from many different sources into or between agricultural crops. The BMSB feeds on fruit causing severe distortions and internal damage making them unmarketable. In 2010, in the Mid-Atlantic States, large populations of BMSB were reported in fruit orchards and, even though pesticides were used, crop losses were high. The evaluation of insecticides for control of the BMSB has shown that very few currently registered products are effective at preventing crop losses. Most of the insecticides that have shown promise against BMSB are in the synthetic pyrethroid class. This class of insecticide has a broad spectrum against pests and is known as being highly toxic to many natural enemies of agricultural pests.

The BMSB is known as a hitchhiker, that is, it likes to crawl into vehicles and packaging, especially in the fall of the year. The BMSB has spread from the eastern states to the western states of Oregon, Washington, and California. It is well established in the Willamette Valley of Oregon and southeastern Washington, where large populations have been reported. The first detection of BMSB in eastern Washington, where a majority of commercial tree fruit is grown, occurred in 2012. Although this first detection does not signal an immediate change in tree fruit IPM programs, it does not bode well for the future. If the only effective control of BMSB are synthetic pyrethroid insecticides, the Washington apple IPM program could lose five decades of progress and return to an era of repeated use broad-spectrum insecticides and a highly disrupted biological control system. Hopefully, research will provide alternative management tactics, including the introduction of natural enemies of BMSB from Asia, or effective pheromone trapping systems that would reduce its movement into crops. A large national research and extension project is currently underway with funding from a USDA-NIFA Specialty Crop Research Initiative grant. The web site of the project provides good information on the progress being made to combat this new and serious threat to IPM in all agricultural crops.

Summary

IPM as a philosophy strives to utilize all available tactics to mitigate the negative impacts of pests. The use of the most powerful and quick-acting tactic, pesticides, is the last line of defense after biological control, behavioral controls, or other tactics have failed to keep pests below levels that result in significant crop loss. Use of tactics, primarily pesticides, is based on the level of a pest present in the crop; therefore, sampling protocols and an understanding of the relationship between a pest level and crop injury is foundational to IPM.

IPM in tree fruit provides a good example of multiple tactics used to suppress key pests while conserving natural enemies that provide control of indirect or secondary pests. IPM programs in tree fruit have changed over the past five decades in response to regulatory action that has limited use of certain pesticides and to the development of new pest control technologies like pheromones and OP-alternative insecticides. IPM is information intensive, requiring an underpinning of sound science coupled with creative and technology-assisted delivery of information. A reduction in human resources in Extension activities at state land-grant institutions makes decision support systems like WSU-DAS even more important to the future of IPM information delivery.

Glossary

Biotechnology The use of biological methods (often genetic engineering and related advanced molecular biology applications) to produce products, processes, and related services. Generally, these are patentable under US patent law.

Commercialization The process of taking an invention or discovery to the marketplace. It involves working the idea into a business plan, consideration of protection options, and determining how to market and distribute the finished product.

Freedom to operate The ability to undertake research or commercial development of a product without infringing the unlicensed intellectual or tangible property rights of others.

Intellectual property (IP) Creative ideas and expressions of the human mind that have commercial value and are entitled to the legal protection of a property right. The major legal mechanisms or protecting IP are copyrights, patents, and trademarks. IP rights enable owners to select who may access and use their IP and to protect it from unauthorized use.

Patent (US) A grant by the federal government to an inventor of the right to exclude others from making, using, or selling his or her invention. There are three kinds of patents in the United States: a standard utility patent on the functional aspects of products and processes; a design patent on the ornamental design of useful objects; and a plant patent on a new variety of a living plant. Patents do not protect ideas but protect only structures and methods in which technological concepts are applied. Each type of patent confers the right to exclude others from a precisely defined scope of technology, industrial design, or plant variety. In return for the right to exclude, an inventor must fully disclose the details of the invention to the public so that others can understand it and use it to further develop the technology. Once the patent expires, the public is entitled to make and use the invention and is entitled to a full and complete disclosure of how to do so.

Plant breeders' rights Rights given to plant breeders to protect new varieties of plants by giving exclusive commercial rights to market a new variety or its reproductive material.

Plant patent In the United States, the Plant Patent Act of 1930 provides a grant of exclusive IP rights to applicants who have invented or discovered a new asexually propagated variety of plant. Tuberous plants are not covered by plant patents.

Plant variety protection A form of patent-like protection for sexually propagated plants as well as hybrids, tubers, and harvested plant parts. The Plant Variety Protection Act of 1970 is administered by the US Department of Agriculture and not the US Patent and Trademark Office (which does issue plant patents).

Public domain The status of an invention, creative work, commercial symbol, or any other creation that is not protected by some form of IP right. Items that have been determined to be in the public domain are available for copying and use by anyone.

Introduction

In the overall agricultural innovation system, there needs to be a balance between exclusive accesses to certain technologies and at the same time ensuring broad access to other technologies. An iconic example of this is the case in the early 1980s when recombinant DNA methods were patented by Stanford University and the University of California (Cohen and Boyer, 1980). This patent, covering the fundamental tool of modern biotechnology, was nonexclusively licensed under reasonable financial terms, a strategy that resulted in licenses to 468 companies (Feldman, 2005). Broad innovation was encouraged through access to the key enabling technologies; many companies became successful by using these tools to develop proprietary products based on other patented technologies that they exclusively held. Ultimately, the licensing strategy enabled US$35 billion in worldwide product sales and brought in US$255 million in licensing revenues (Feldman, 2005).

In agriculture today, the innovation system benefits by a balance of both exclusive and nonexclusive access to patented technologies to effectively support new technology development and to provide both commercial growers and subsistence farmers with the best technology possible for their crops. The ownership of critical IP and the rights to practice or use certain technologies is becoming a major issue confronting researchers in this area. Even purely fundamental academic research is not protected by an 'experimental use' exemption from patent infringement and may become increasingly entangled in issues involving access to IP rights (Eisenberg, 2003). Although the importance of IP in agriculture is becoming better recognized in both the public and the private sectors, many researchers, business people, research and development decision makers, and policy makers are still relatively uninformed about how to find, understand, and utilize IP information, including published patents and patent applications. Here an overview of the major issues and what a research scientist needs to be aware of when navigating the

agricultural IP landscape is provided. This topic had been reviewed previously and additional information can be found in those reviews (Chi-Ham and Bennett, 2011; Chi-Ham *et al.*, 2010; Bennett *et al.*, 2008).

What Is Intellectual Property?

IP is a form of property that applies to your ideas or the 'products of the mind' and gives the owner a set of rights that are, in some ways, comparable to tangible property rights. The concept of IP was insightfully addressed by Thomas Jefferson when he said: "If nature has made any one thing less susceptible than all others of exclusive property, it is the action of the thinking power called an idea, which an individual may exclusively possess as long as he keeps it to himself...Inventions then cannot, in nature, be a subject of property. (However) society may give an exclusive right to the profits arising from them, as an encouragement to men to pursue ideas which may produce utility" (Jefferson, 1903). Jefferson's concept of society providing a legal mechanism for inventors to have an exclusive right to profits from their ideas was subsequently integrated into the US Constitution, Article I, section 8, which states that "The Congress shall have power... to promote the progress of science and useful arts by securing for limited times to authors and inventors the exclusive right to their respective writing and discoveries." This forms the basis for IP rights and has become the cornerstone of the innovation process in the United States and more recently in many other countries throughout the world.

Intellectual Property and Agricultural Research

The impact of public sector research in agriculture has been very significant. In the United States, this dates back to the establishment of the Land Grant system of universities that has led the development of improved crop varieties, which were transferred to farms and the agricultural industry through cooperative extension services. Internationally, the system of crop research centers sponsored by the Consultative Group on International Agricultural Research has had a similarly large impact in developing new crop cultivars and agronomic practices that were delivered as a public good to support global food production (Table 1).

This model of public sector agricultural research has been slowly changing and the rate of change is now accelerating. At the core of this change is the increasing role of IP protection over agricultural inventions as well as the development of a research-intensive private sector in agricultural biotechnology. Thus, both United States and global agricultural systems are experiencing a change from research results being developed primarily in the public sector and the resulting technologies delivered for free as a public good to a system that is increasingly dominated by private companies who protect and treat results as a private asset. This has been accomplished through a much more intensive use of the patent system to protect agricultural innovations than was previously the case. The trend in patents awarded related to plant biotechnologies between 1980 and 2000 (Graff *et al.*, 2003) clearly illustrates the overall increase in patenting activity in this sector and this trend has continued in the authors' recent analysis (Figure 1).

In the past 25 years, other fundamental changes in the nature and ownership of innovations in basic and applied agricultural research have complicated the mission of public research institutions. The primary change was galvanized by the passage of the Bayh–Dole Act that effectively encouraged US universities to patent their innovations and license them to private sector companies in order to encourage their commercial use. Since that time, patenting by public research institutions and universities as well as the development of formal technology transfer mechanisms has accelerated. Although, by the 2000s, public sector institutions were contributing only approximately 2.7% of patents overall, their contribution to agricultural biotechnology patents is nearly an order of magnitude greater – contributing approximately 24% of all patents (Graff *et al.*, 2003). Although this trend has contributed to many positive economic outcomes, these new policies have created challenges for public research institutions and universities in supporting broad innovation, particularly for agricultural applications that address small markets, such as specialty crops, or that support humanitarian, rather than commercial, purposes.

Types of Intellectual Property in Agriculture

The main types of IP protection applicable to agricultural inventions include patents, plant variety rights, trade secrets, trademarks, and copyrights (Kesan, 2007; Dodds *et al.*, 2007). Tangible property rights are another class of property and are often captured in material transfer agreements (MTAs), bailments, or legal contracts that protect the exchange and use of physical materials. These forms of IP rights are the cornerstone of the innovation process in the United States and Europe, and the rights are increasingly expanding into other countries in the world.

Patents provide the legal rights to exclude others from using your invention. Patent rights are conferred by national governments for a specified period of time, usually 20 years, and are limited to the country in which the patent is granted. In exchange for exclusivity, the inventor makes a public disclosure of the invention. The monopoly that a patent provides to an inventor can be a powerful economic right and, as a consequence, the invention must meet a relatively high set of legal standards, which include (1) novelty, (2) nonobviousness, and (3) utility; that is, the invention (1) must be original and not previously known or published, (2) it must not be an obvious extension of previously known information, and (3) the invention must have some useful purpose. The legal standard of novelty has an important implication for public sector researchers because the primary means of scientific communication is through broad publication that, if done carelessly, can make an invention 'known' and thus destroy its patentability. The section of US patent law that lays out the novelty standard says that a patent application can be rejected on lack of novelty grounds if "the invention was… patented or described in a printed publication in this or a foreign country, before the invention thereof by the applicant for patent, or… More than one year prior to the date of the application for

Table 1 Overview of IP protection system

Means of protection	*What can be protected*	*How to protect*	*Term of protection*	*The rights of the owner*
Utility patent	Any useful, novel, and nonobvious invention	USPTO	If filing date is after 8 June 1995, 20 years from filing date; if filing date is before 8 June 1995, 17 years from issue date	Right to exclude others from making, using, manufacturing, selling, and offering to sell
US Plant Patent	Asexually produced plants (excludes uncultivated and tuber-propagated plants)	USPTO	If filing date is after 8 June 1995, 20 years from filing date; if filing date is before 8 June 1995, 17 years from issue date	Right to exclude others from asexually reproducing, selling, or using claimed plant
US and PVP	Sexually produced plants (excludes first generation hybrids and uncultivated plants)	USDA	20 years for most crops; 25 years for trees and vines	Right to exclude others from importing or selling, sexually or asexually reproducing, distributing without proper notice, producing a hybrid or new variety, and using the claimed patent
UPOV91	All genera and species	UPOV	20 years for most crops; 25 years for trees, shrubs, and vines	Prevents others from producing or reproducing, conditioning for the purpose of propagation, offering for sale, selling or other marketing, importing, exporting, and stocking for any purposes
Trademarks	Words, phrases, and logos that can distinguish the goods and services from those of others	Use or have a bona fide intent to use and apply for a federal registration	Unlimited duration as long as the mark is in use; the mark has to be renewed every 10th year	Right to exclude others from using the mark and other marks so similar that they cause confusion
Copyright	Literary works, software, dramatic works, music, pictures, sound recordings, architectural works, and movies	Apply for federal registration	Life of the author plus 70 years	Right to prevent unauthorized copying or public performance
Trade secrets	Any technical or business information that is secret and that gives the holder an advantage over a competitor who does not have the information	Keep secret; no registration available	Unlimited duration as long as the subject matter is secret	Right to prevent unlawful use

patent in the United States." The 1-year grace period provided in the United States does not exist in most other countries and public disclosure of an invention immediately bars patentability in those countries. This has especially been important since 16 March 2013, when the Leahy–Smith America Invents Act (AIA) was implemented as US patent law. The AIA transformed the US patent system from a first-to-invent system to a first-to-file system involving changes that make US patent law more consistent with the European Union and other nations to yield greater consistency and predictability in obtaining and enforcing patent rights across countries. Overall, the new first-to-file regime provides an incentive to file a patent application as early as possible. In addition to the timing of public disclosures, a researcher should consider the meaning of the words printed and publication. For example, is a report, a meeting proceeding, or a slide presentation posted on the Internet considered printed, such that the document bars future patentability? Any disclosure of a potentially patentable idea should be made thoughtfully and in consultation with an attorney or technology transfer office. In some cases, an intentional public disclosure can be purposely designed to bar patentability by others, in order to ensure that an invention remains in the public domain and available for everyone to use without IP restrictions (Boettiger and Chi-Ham, 2007).

In the United States, the two forms of patents most pertinent to the agricultural industry are plant patents and utility

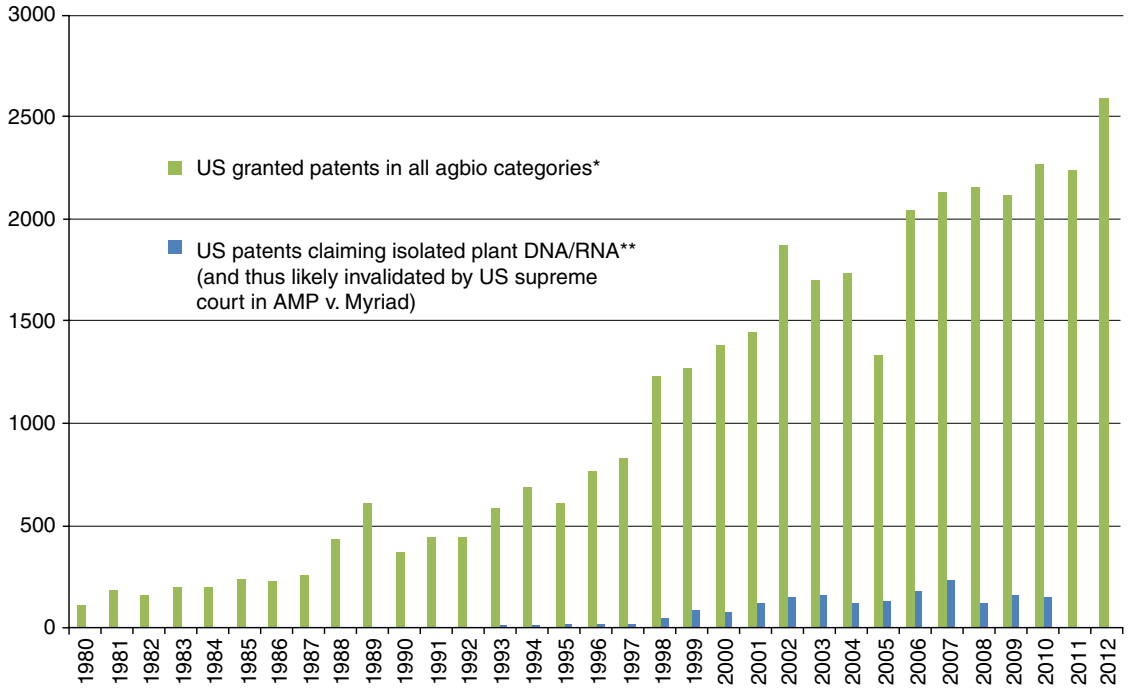

Figure 1 Annual Trends in Plant Biotechnology based on patents granted between 1980 and 2012. *Note*: Analysis includes *US patents granted and corresponding to the international patent class categories considered relevant in agricultural biotechnology (green bars, reproduced from Thomson Innovation, 2013, Available at: http://info.thomsoninnovation.com/en/features/search (accessed 07.05.14).). **US patents claiming isolated DNA/RNA sequences that are likely to become invalidated by the US Supreme Court, Reproduced from Graff, G.D., Phillips, D., Lei, Z., *et al.*, 2013. Not quite a myriad of gene patents. Nature Biotechnology 31, 404–410.

patents. Plant patents are unique to the US legal system and are granted only for plants that are asexually propagated, by cuttings or other means, such as strawberries or grape vines. At the time the US Plant Patent Act was enacted in the 1930s, sexually produced plants were believed to be unstable and nonuniform and as a result were excluded from plant patent protection. Utility patents offer one of the most robust forms of IP protection. In agricultural biotechnology, utility patents can be used to protect the genetically modified seeds or plants and the methods embodied in the invention, such as plant transformation and selection methods. Utility patents may protect different aspects of the invention. For instance, in the 1990s, Calgene Inc., now a part of Monsanto Company, used utility patents to protect the first agricultural biotechnology crop, the FlavrSavr™ tomato, which was genetically engineered to suppress expression of the tomato fruit-ripening polygalacturonase enzyme. Using a portfolio of patents, the company protected the DNA sequence of the enzyme, a DNA construct to suppress the enzyme expression in plants, the transgenic tomato cell, and even the overall method for antisense-based gene suppression of this or any other gene. In the United States, the US Patent and Trademark Office (USPTO) awards both plant and utility patents.

Plant Breeder's Rights (PBR) are a somewhat weaker form of IP for plant breeders, which, like patents, are granted nationally. In the United States, PBR are provided by plant variety protection (PVP) certificates issued through the US Department of Agriculture. PBRs are defined by a widely employed international agreement initiated by Europe, called the International Union for the Protection of New Varieties of Plants but commonly referred to by its French acronym UPOV (Lesser, 2007; Kesan, 2007). The original International Convention that established UPOV was held in 1961 and the treaty has been subsequently revised in 1972, 1978, and more recently in 1991. UPOV provides an international standardized framework according to which each member government can establish its own national legal system for PBRs. UPOV requires that a plant variety meets a set of criteria known as the DUS requirements: it must be distinct, uniform, and stable.

The agricultural industry can use a combination of plant patents, utility patents, PVP, and PRBs to protect and market new crop varieties in most parts of the world. Notably, in the United States it is possible to get dual protection for plant varieties through a utility patent and a plant patent, or through a utility patent and a PVP certificate, but not a plant patent and a PVP certificate as these cover either asexually or sexually propagated plants, respectively (Pardey *et al.*, 2013). For example, the University of California relies on US plant patents domestically and UPOV-based PBRs internationally to manage a successful Strawberry Licensing Program in domestic and international markets. The Strawberry Licensing Program has expanded internationally into countries with strong IP protection and the California-bred strawberry cultivars now represent up to 60% of the worldwide production (Bennett and Carriere, 2007).

In some cases, the dual protection through utility patents and PBRs has generated tensions because exemptions in one system are often not available under the other. For example, under PBR systems there is commonly an exemption for farmers to save and replant seed, which is not acceptable under

patent law. This was recently reinforced by the US Supreme Court in the decision Monsanto v. Bowman, which held that patent rights extend to the progeny grown by a farmer if those progeny still contain the patented genetic traits.

Trade secrets are an additional form of IP protection and one of the oldest. Trade secrecy is used to protect confidential business information, processes, know-how, data, and materials. However, a trade secret does not protect against the reverse engineering of a product by competitors. In the seed industry, trade secrets are used to protect parent inbred corn lines that are used to produce hybrid seed but are clearly not useful for the protection of a variety that can be directly propagated asexually or with open-pollinated seeds. Where appropriate, however, trade secrets can be maintained indefinitely so long as confidentiality is never breached.

Another form of IP protection, however, of limited utility in agriculture, is copyright. Copyright protects the expression of an idea, such as such as descriptions or diagrams, or other materials such as might be displayed in catalogs or seed packages. This form of IP protection is weaker than others because anyone is free to use the actual plant or the underlying depicted idea. Also, anyone is permitted to use the copyrighted information for the development of a product. In the United States, copyright protection is awarded for the life of the author plus an additional 70 years. Copyright use in plant sciences is, however, increasing because the plant genome information in electronic database can be subject to copyright protection.

Trademarks are another form of IP protection applicable to brand names of agricultural products; however, as with copyright it does not protect the underlying technology itself. In the United States, trademarks are registered at the USPTO. A searchable database of trademark registrations is available on the USPTO website at the Trademark Electronic Search System. For crops, trademarks are often used to protect any word, phrase, symbol, or logo that represents brand varieties or products, such as Dole® (a registered trademark of Dole Fruit Company), Sunkist™, and Monsanto Company's Roundup Ready® products.

Tangible property rights reside with the property owner and the terms of tangible property transfer are usually captured in MTAs or bailments, which both are legal contracts that allow the transfer of the 'physical' property while ensuring that the initial owner retains rights of physical ownership of the material. In research, MTAs are often used for transfer of materials for only research use, allowing scientists to perform academic research. However, there is typically no guarantee or promise that the owner will give rights for commercial applications. Also, the property owner can establish the time period and geographical limitations. Research use only MTAs are typically easier to obtain, especially between public or nonprofit research institutions but could represent considerable obstacles downstream if the materials cannot be used for commercial applications.

The patenting of plant and animal genes has been particularly controversial and critics have argued that genes are not patentable because they exist in nature. The USPTO has maintained since the 1980s that an isolated and purified deoxyribonucleic acid (DNA) molecule that has the same sequence as a naturally occurring gene is eligible for patent protection because it does not occur in its isolated form in nature. However, on 13 June 2013 the Supreme Court ruled in the case AMP v. Myriad Genetics that even if isolated, natural DNA is still a product of nature and therefore cannot be patented. The rationale of the ruling was that the location and order of the nucleotides existed in nature before anyone discovered them. This ruling has major implications because it will no longer be possible in the United States to patent or exclude others from using a naked genomic DNA molecule. However, interestingly the Court also ruled that a complementary DNA (cDNA) sequence is patent eligible because it is created from an messenger ribonucleic acid (mRNA) molecule as an exon-only DNA molecule that is not naturally occurring; more importantly the decision does not eliminate the ability to patent more complex DNA constructs.

Already in 2001, the USPTO began tightening the standards for granting of gene patents, by modifying and adopting a higher standard of 'utility' in its guidelines for evaluating gene patents, requiring that the applicant demonstrates that the 'utility is specific, substantial, and credible.' In spite of this specific utility requirement some patent applications have continued to seek to claim the sequences of hundreds of genes for which the utility is only broadly defined. For example, US patent application 20070022495 defines the utility of several hundred claimed genes as conferring an 'improved trait relative to a control plant' and "the improved trait is selected from the group that consists of larger size, larger seeds, greater yield, darker green color, increased rate of photosynthesis, more tolerance to osmotic stress, more drought tolerance, more heat tolerance, more salt tolerance, more cold tolerance, more tolerance to low nitrogen, early flowering, delayed flowering, more resistance to disease, more seed protein, and more seed oil relative to the control plant." The USPTO, however, significantly limited the scope of the claims of this broad application on granting the patent in 2010.

Based on the ruling by the US Supreme Court in AMP v. Myriad, a number of US-granted patents that include claims to isolated nucleic acids are likely invalidated (**Figure 1**).

Proliferation of Patents in Agricultural Biotechnology

The proliferation of patents in medical biotechnology led to the development of a metaphor to explain why people overuse or under use resources. The 'tragedy of the commons' was a term coined by Garrett Hardin to explain why people overused shared resources, such as common pastures, because they have no incentive to conserve or extend to the life of the resource (Hardin, 1968). By analogy, Heller and Eisenberg (Heller and Eisenberg, 1998) described the 'tragedy of the anticommons,' which, as a result of a proliferation and fragmentation of IP ownership across multiple owners, prevents any single institution or company from assembling all of the necessary rights to produce a product, resulting in underuse (or nonuse) of resources. Interestingly, although patents and IP generally are intended to encourage investment in research and development, the development of an anticommon has the opposite effect of blocking innovation. Although this concept of the anticommons was initially described in relation to

biomedical research, it also has direct relevance to agricultural biotechnology.

A prominent example of the complexity resulting from fragmented technology ownership and the potential for anticommons to arise was exemplified in the development of *β*-carotene-enriched rice by public-sector researchers who used at least 40 patented or proprietary methods and materials belonging to a dozen or more different owners in the gene transfer process (Kryder *et al.*, 2000). Some examples of the types of patented technologies that are required for developing a genetically engineered crop are discussed in the following sections.

Transformation Methods

The development of transgenic varieties has typically relied on either *Agrobacterium*-mediated or biolistic-mediated gene transfer methods (Herrera-Estrella *et al.*, 1983; Klein *et al.*, 1987). The breakthrough achievement in developing *Agrobacterium*-mediated gene transfer technology earned Van Montagu, Chilton, and Fraley the 2013 World Food Prize. Fundamental methods related to both processes of gene transfer into plant cells were developed in the public sector (Barton *et al.*, 2000; Sanford *et al.*, 1991), but key patents for *Agrobacterium*-mediated transformation are owned exclusively by Monsanto and others were licensed exclusively to Ciba-Geigy (now Syngenta) and the biolistic technology was licensed exclusively to DuPont for most fields of use. In addition, both private and public sector research and development organizations have patented a number of fundamental transformation methods as well as improvements, including vectors, species-specific protocols, and novel strategies to remove selectable markers and other 'foreign' DNA from the plant to be commercialized (Hamilton, 1998; Hoekema *et al.*, 1992; Frayley *et al.*, 1991; Rogers and Fraley, 2001). As a result of a variety of transactions, fundamental methods of gene transfer to plant cells were invented either by private sector companies or by the public sector but then licensed exclusively to private companies and represent a key technology area where patents have the potential to block new innovations. An example is the recently granted US 8,273,954 (Rogers and Fraley, 2001) patent covering a broad *Agrobacterium*-mediated transformation method for dicotyledonous plants, which is owned by Monsanto and has an anticipated expiration date in 2029. The effective filing day of the initial patent application was 17 January 1983; however, the pending application was not granted for approximately 30 years due to an interference case in which two applicants had claimed the same invention. Finally, in September 2012, Monsanto was granted the patent, which has a term of 17 years from the issuance date under US patent law, based on the fact that the original patent application was filed before 8 June 1995, the pre-General Agreement on Tariffs and Trade Treaty (GATT)–Agreement on Trade Related Aspects of Intellectual Property Rights filing date (**Figure 2**). The scope of Monsanto's patent is a method for transforming dicotyledonous plant cells with any coding sequence genes, including selectable markers, using *Agrobacterium* and a Ti plasmid with *Agrobacterium* transfer DNA borders. Monsanto Company announced that it would provide a royalty-free research license to the academic community and other nonprofit research institutions for the *Agrobacterium* transformation method newly issued patent US 8,273,954. The company also announced that it would continue to make commercial licenses available.

There has been a growing interest in non-*Agrobacterium*, bacterial-mediated transformation. One of the first viable alternative plant transformation methods to *Agrobacterium*-mediated transformation and biolistics was the Transbacter™ suite, developed by the Center for Application of Molecular Biology for International Agriculture (CAMBIA). Transbacter™ was introduced in 2005 by CAMBIA as a new plant transformation technology using non-*Agrobacterium* bacteria. CAMBIA filed a number of patents; however, the portfolio has been abandoned and the technology is now in the public domain. Recently, a research group based at Teagasc Crop Research Center (The Irish Agriculture and Food Development Authority) discovered an alternative bacterial plant transformation method to the classical *Agrobacterium*-mediated transformation using Ensifer adhaerens, a Gram-negative soil bacterium capable of a horizontal gene transfer that is genetically distinct from *Agrobacterium* (Mullins *et al.*, 2013; Wendt *et al.*, 2012).

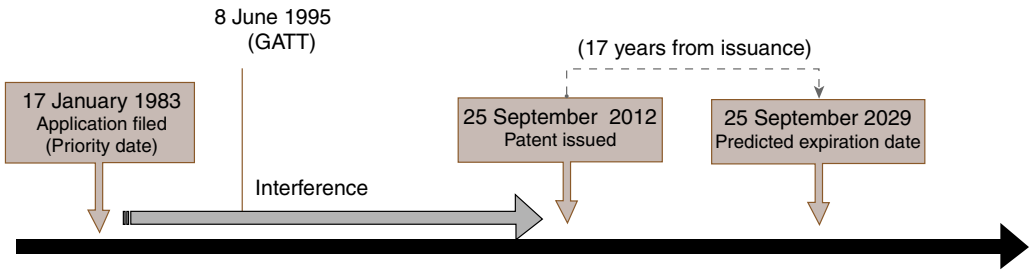

Figure 2 Prosecution of Monsanto's *Agrobacterium*-mediated transformation of dicot plants US patent 8,273,954. Although the patent application was filed in 1983, prosecution was delayed due to an interference case. The patent was awarded on 25 September 2012; however, because the application date was before 8 June 1995, the expiration date is calculated 17 years from the issue date. On 8 June 1995 the US patent law passed a major change to harmonize US law with other countries' law, the GATT. Before 8 June 1995 a US patent had a term of protection lasting 17 years from the date of issuance. Under GATT changes, an unexpired issue patent or a patent application pending on 8 June 1995 has a term of protection of 17 years from the date of issuance of the patent or 20 years from the filing date of the patent application, whichever is longer, which is the case for the US 8,273,954 patent. Any patent application filed on or after 8 June 1995 has a term of protection that begins on the date of the grant of the patent and ends on a date 20 years after the filing date of the patent application.

Ensifer-mediated transformation (EMT) exhibits transformation efficiencies that are comparable with *Agrobacterium*-mediated transformation, and more importantly can be directly substituted into existing *Agrobacterium* protocols without further optimization and may be used with both dicot and monocot plants. The Tegasc EMT patent portfolio currently includes an international patent application WO 2011076933 and two pending patent applications, US 20130078706 and CA 2784550 in the United States and Canada, respectively. These public sector inventions may represent alternatives for plant transformation.

Selectable Markers

The most commonly utilized plant selectable marker genes include the neomycin phosphotransferase II (*nptII*) and hygromycin phosphotransferase (*hpt*) genes that confer antibiotic resistance as a basis to select cell transformation (Miki and McHugh, 2004). Several other selectable markers conferring herbicide resistance or positive selection based on novel carbon utilization pathways provide important alternatives to the antibiotic-based selection strategies (Roa-Rodriguez and Nottenburg, 2003).

Historically, Monsanto held the broadest patent portfolio for use of selectable markers for plant transformation. Until 2008, Monsanto's patent on kanamycin-based plant selection (US 6,174,724) limited freedom to operate (FTO) for this enabling technology (Chi-Ham *et al.*, 2012). Because kanamycin is Generally Recognized as Safe, it is a desirable selection method from a technical, regulatory, and, now, and IP position.

Novartis AG (formerly owned by Eli Lilly & Company) owns an international patent portfolio protecting the method of selecting hygromycin-resistant plants, which includes two active issued US patents, US 5,668,298 and US 6,048,730, with a predicted expiration date of September 2014. Bayer CropScience (formerly Aventis CropScience) holds a patent portfolio with active issued US patents covering different components of the phosphinothricin-based herbicide selection method, including US 5,561,236, US 5,648,477, and US 5,646,024, which have predicted expiration dates of October 2013 and July 2014 for the latter two, respectively.

Selection strategies appear not to have been the topic of public sector research programs and there are just a few examples of either public domain or public sector-patented selectable markers for use in plant transformation (Dirk *et al.*, 2001; Dirk *et al.*, 2002; Mentewab and Stewart, 2005b; Mentewab and Stewart, 2005a; Hou *et al.*, 2006). Although there is potential to invent new selectable markers for plant transformation, at this point most of the broader patents have expired and there is potential to obtain FTO using public domain selectable markers.

Constitutive Promoters

Genetic regulatory elements are required to drive the expression of selectable marker genes and of specific transgenes. Selectable marker genes are typically driven by high-level constitutive promoters with the most common constructs utilizing the cauliflower mosaic virus (CaMV) 35S promoter derived from a viral genome and patent rights formerly owned by Monsanto, now expired (Chi-Ham *et al.*, 2012; Odell *et al.*, 1985). There are many promoters that confer constitutive gene expression which were developed in public sector organizations and either are in the public domain or can be licensed for nominal fees. These alternatives include: monocot and dicot actin promoters (Lemaux *et al.*, 2005; McElroy *et al.*, 1990; An *et al.*, 1996), an figwort mosaic virus (FMV) 34S promoter (Comai *et al.*, 2000), mannopine/octopine synthase (Gelvin *et al.*, 1999), or FMV and peanut chlorotic streak caulimovirus full-length transcript promoters (Maiti *et al.*, 1997; Maiti and Shepard, 1999). The FMV 34S has been used to drive constitutive gene expression and reported to be essentially equivalent to the CaMV 35S promoter (van der Fits and Memelink, 1997; Romano *et al.*, 1993) but has not been widely distributed to the public sector research community. Each of these promoters provides a strategy for driving constitutive transgene expression using public sector-derived or public domain components.

Tissue- or Developmental-Specific Promoters

Although many genes can be expressed under the control of constitutive promoters, targeting of expression to plant organs or tissues is typically desirable to minimize nonspecific effects of the introduced gene. For example, seed-specific promoters (Blechl *et al.*, 1999; Harada *et al.*, 2001) have been patented with claims directed toward their use to drive expression of heterologous genes in developing seeds. Public sector institutions have also patented a relatively large number of tissue- and developmental-specific promoters. Examples include the root-specific CaMV 35S fragment A promoter (Benfy, 1992), a root cortex-specific promoter (Conkling *et al.*, 1998), the Pyk10 root-specific promoter (Grundler *et al.*, 2001), an epidermal cell-specific Blec promoter (Dobres, 1998), and a vascular tissue-specific promoter rice tungro bacilliform virus (Beachy, 1998). In addition, there exists a large number of tissue and developmental specific promoters that have been characterized and placed in the public domain through publication. A wide range of constitutive and regulated promoters have been tabulated in a promoter database that includes information on expression characteristics as well as their IP status.

Subcellular Localization

In addition to specificity in tissue-level transgene expression, it is also often important to direct the targeting of the new protein to a specific subcellular location. For example, because β-carotene is produced in the plastids, the development of β-carotene-enriched rice utilized a transit peptide derived from the small subunit of Rubisco to target proteins to this subcellular compartment (Ye *et al.*, 2000). This and other transit peptides have been the topic of intense study, and several companies have patented their use to direct proteins into plastids (Herrera-Estrella *et al.*, 1983). For example, Plant Genetic Systems (now owned by Bayer) owned a broad patent family, including US 5,717,084 patent, covering a chimeric

DNA sequence that comprises any plant origin transit peptide for chloroplast targeting, with a predicted expiration date of February 2015. In addition, a French company, Rhone Poulenc Agrochimie, owns a US patent recently reissued, USRE 36,449, with narrower scope covering a plant carrying a DNA construct using a double transit peptide with an N-terminal domain of Rubisco. Therefore, in spite of several early publications from public sector research organizations describing alternative transit peptides that were not subsequently patented and thus should be accessible in the public domain, due to the broad claims of the Bayer patent family, using the alternative transit peptide would likely still fall within the scope of Bayer patent family as long as they are of plant origin. Targeting other subcellular locations has been the topic of intense research in both the public and the private sectors and there are many examples of public sector research describing unpatented sequences targeting proteins to a variety of subcellular sites, including the cell wall, vacuole, plastids, and peroxisomes (Komarnytsky *et al.*, 2000; Tague *et al.*, 1990; Volokita, 1991; Hayashi *et al.*, 1996; Bednarek *et al.*, 1990).

Developing a new genetically engineered crop requires the assemblage of a number of patented technologies through in-licensing or, potentially, by a series of strategic mergers and acquisitions. Several companies have effectively done this and have used platforms of proprietary technologies to develop new varieties of major crops. However, work on crops of less commercial interest has progressed slowly with few of the benefits of biotechnology having been realized in specialty crops (Clark *et al.*, 2004). Based on the requirement for assembling a large number of patented technologies to produce genetically engineered crop and the fragmentation of IP ownership, it appears that the preconditions for the development of an anticommons exist in this technology sector. In addition, the observed slowdown in the development of new agricultural biotechnology products may be, at least in part, an effect of such an IP anticommons (Graff *et al.*, 2009).

Freedom to Operate for Agricultural Research and Commercialization

Navigating the complex IP landscape of a research project in agriculture requires some analytical tools and specialized analytical capabilities (Fenton *et al.*, 2007). Although the importance of FTO analyses apply to all areas of agricultural research, they are especially important in the area of agricultural biotechnology where there are a large number of patented technologies. The analysis requires both legal and scientific knowledge as well as access to both patent and literature databases and typically takes the form of what is known as a FTO opinion. The FTO opinion is a legal assessment about whether research project or the development of a new product can proceed with a low, or tolerable, likelihood that it will not infringe existing patents or other types of IP rights. It is important to note that the FTO determination is not absolute but reflects an evaluation of risk because there is typically some uncertainty around the interpretation of patent claims as well as uncertainty as to whether new IP may issue or be discovered at a later date. The FTO opinion may lead to a range of options: identifying in-licensing targets, considering the substitution of technologies, deciding to ignore the potential infringement, investing in work-around technologies, or perhaps deciding to abandon the project all together. Although private firms are more likely to engage in FTO analysis because any infringement risk may directly affect their ability to develop new products and their ultimate profitability, public and not-for-profit private institutions are becoming increasingly aware of the need for better FTO information. This is particularly true for research projects undertaken by universities or not-for-profit research centers for the specific purpose of developing new crops for developing countries. In these cases, it is critical that IP considerations be taken into account early in the research process.

Although patents are the most common type of IP rights encountered, a thorough FTO analysis will assess all types of existing property rights for the likelihood that the research project or the product being commercialized infringes. Of particular concern are tangible property rights, such as cell lines, transgenic plants, germplasm, and plasmids. Because, the transfer of tangible property often occurs under the terms of a MTA that has no geographic or temporal limitation, these terms can be particularly problematic and directly impact FTO.

Enabling technologies for plant transformation or transformation vectors combines several components, such as promoters, selectable markers, marker removal systems, and more. Because of the fundamental role of these technologies, they have been extensively patented. In addition, the FTO surrounding plant enabling technologies is further complicated because these technologies are not used individually but are combined with a suite of related enabling technologies and specific trait technologies and are deployed in many different plant species. A single component of a transformation vector is a relatively simple example that illustrates the elements of an FTO analysis.

The target technology for this case study was a fruit-specific promoter from the tomato *E8* gene. The E8 promoter has been used to improve fruit quality, to extend fruit shelf life, and to express edible human vaccines specifically in ripening tomato fruit. The first step in an FTO investigation is to clearly define the target technology. In this hypothetical case, the fruit-specific promoter will be used exactly as described in the initial publications by Deikman and Fischer (1988), Deikman and Fischer (1988), Giovannoni *et al.* (1989), and Giovannoni *et al.* (1989). The promoters in these publications are virtually identical and consist of approximately 2100 nucleotides upstream of the *E8* structural gene. Further promoter characterization identifying the location and sequence of functional elements within the promoter and upstream nucleotide sequence was reported in Deikman *et al.* (1992). These publications draw the technical boundaries surrounding the target promoter technology and provide important prior art to subsequently filed patents.

To establish the relationship of publications and patents that describe or claim the E8 promoter, a patent landscape must first be established. The patent landscape should include patents and patent applications closely related to the technology. Keywords and authors of key publications are used to search for patents or patent applications. A separate search should then be conducted to identify patents or patent applications that referenced the scientific publications describing

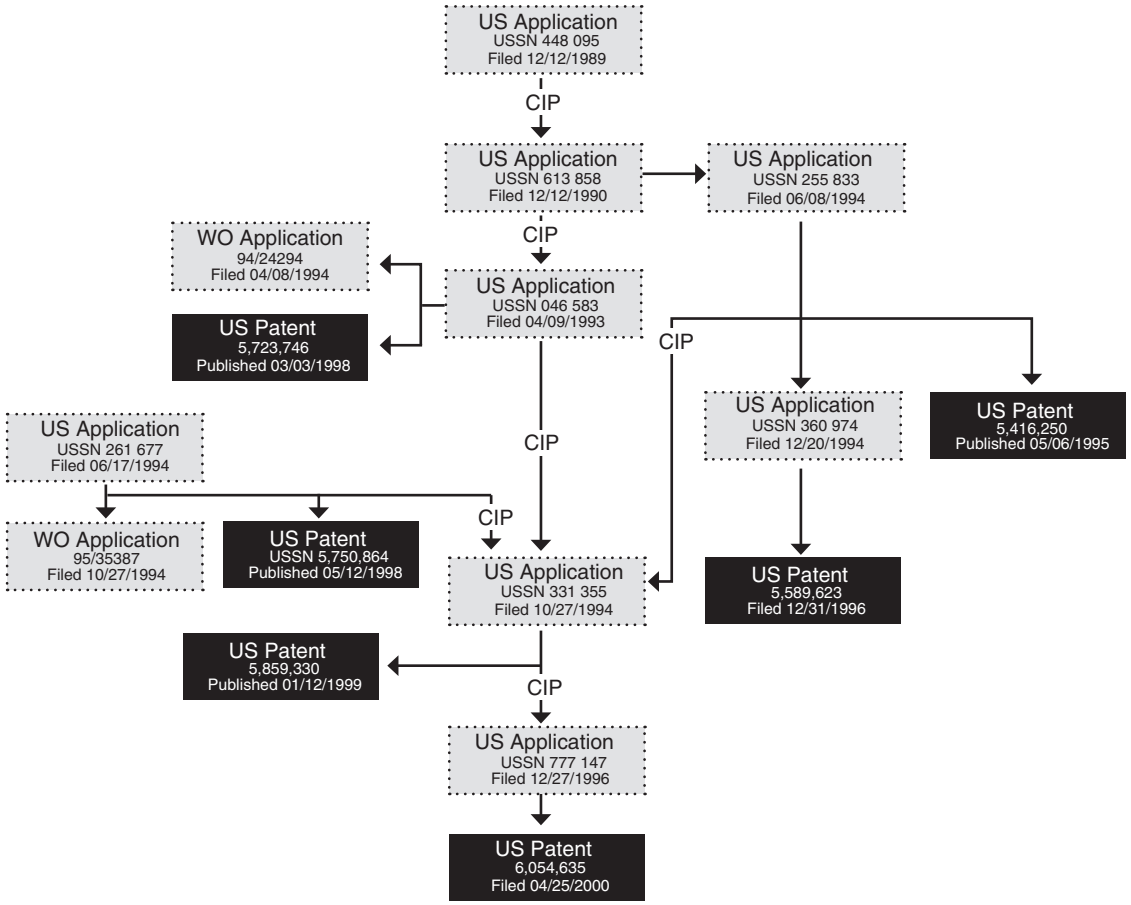

Figure 3 The Epitope/Agritope Patent Family related to the tomato E8 promoter. Patent applications are shown in gray, including US and WO or PCT applications; and issued US patents are shown in black. Modified from Fenton, G., Chi-Ham, C., Boettiger, S., 2007. Freedom to operate: The law firms approach and role. In: Krattiger, A., Mahoney, R., Nelsen, L., *et al.* (Eds.), Intellectual Property Management in Health and Agricultural Innovation: A Handbook of Best Practices. Oxford, UK: MIHR. Davis, CA: PIPRA, pp. 1363–1383.

the technology. Additionally, in the E8 case, patented DNA and protein sequence databanks were searched using the promoter's DNA sequence as a query. The patent landscape will reveal 'family' relationships among different patents and published patent applications. Patent families include later patent applications that claim the benefit of an earlier, related application or later, patent applications that arise from foreign filings of the patent application. Figure 3 illustrates a patent family arising from a 1989 patent application related to the E8 promoter filed by Agritope, an agricultural biotechnology company.

An informative way of analyzing the FTO search results is to construct a timeline of scientific literature, patent applications, and issued patents on the specific technology and on potentially overlapping subject matter. Ordering the patents and published applications according to their priority dates (also known as effective filing dates) reveals important relationships. For example, it reveals what publications or patents are prior art against newer patents. As patents may only be granted if the claims are both novel and nonobvious over the prior art, this analysis reveals the relative dominance of earlier, broader patents over later, narrower patents. Figure 4 illustrates the IP priority timeline for the E8 promoter. A thorough FTO analysis may require direct contact with the researchers and, in this analysis, it was learned from the authors of the Deikman and Fischer publication (1988) (Deikman and Fischer, 1988) that they did not apply for patent protection before their publication. This information was also confirmed by searching patent databases. Based on this information, it was presumed that the basic E8 promoter technology was in the public domain, but this conclusion required thorough review and documentation of the published literature or 'prior art' relative to the subject matter of subsequent patents.

As shown in the priority timeline, the Deikman and Fischer (1988), Deikman and Fischer (1988), Giovannoni *et al.* (1989), and Giovannoni *et al.* (1989) publications initially describe the E8 promoter technology. This precluded the novelty of any subsequent patent claims on the E8 promoter per se (e.g., applications filed by Agritope and Epitope). Counsel concluded that the tomato E8 promoter constructs per se could be reasonably considered to be in the public domain. However, some of the subsequent patents claim chimeric constructs that comprise the E8 promoter and heterologous genes and use of the E8 promoter in conjunction with other promoter elements. Thus, certain specific uses of the E8 promoter may infringe these subsequent patents.

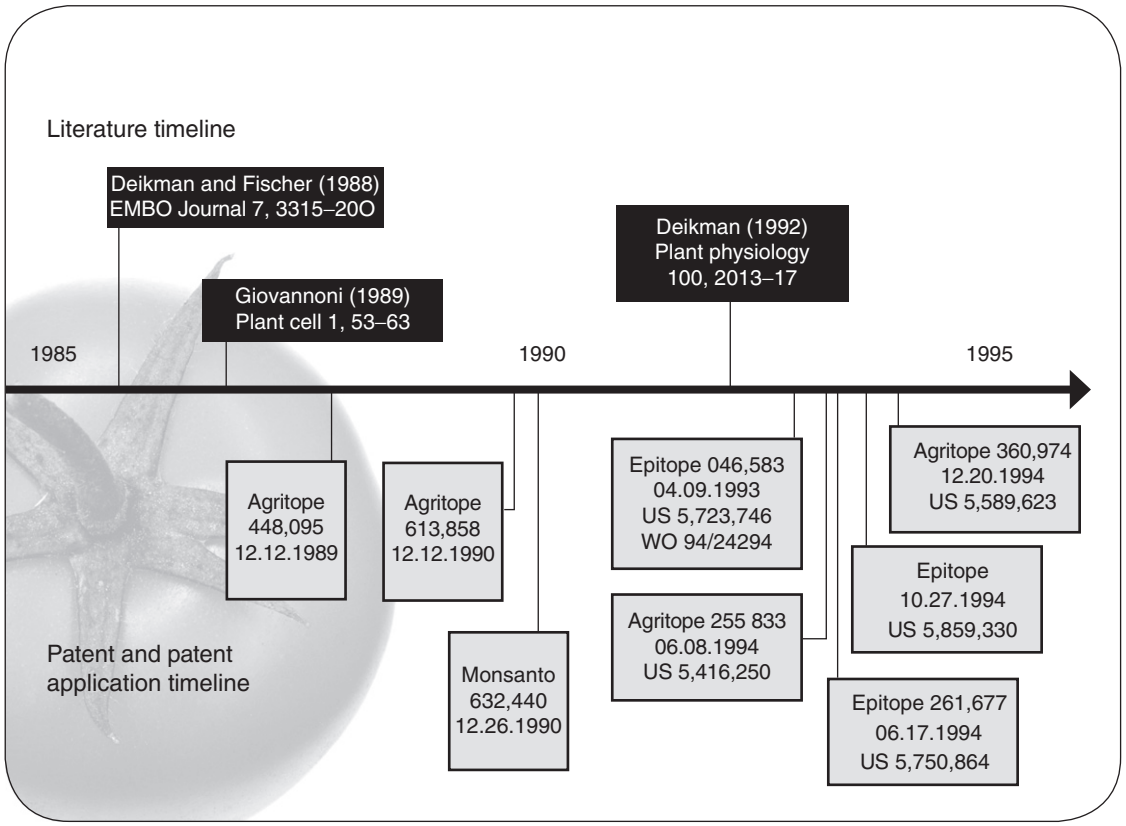

Figure 4 Timeline of the Tomato E8 promoter scientific publications and patents. Dates of publication of research articles are shown in black boxes above black timeline arrow, and priority date or effective flinging date of the issued US patents associated to the Tomato E8 promoter are shown in gray below the back time line. Modified from Fenton, G., Chi-Ham, C., Boettiger, S., 2007. Freedom to operate: The law firms approach and role. In: Krattiger, A., Mahoney, R., Nelsen, L., *et al.* (Eds.), Intellectual Property Management in Health and Agricultural Innovation: A Handbook of Best Practices. Oxford, UK: MIHR. Davis, CA: PIPRA , pp. 1363–1383.

This example provides an overview of the data and information that should be considered in an FTO analysis. It is not difficult to imagine how the complexity of an FTO analysis would grow dramatically with the inclusion of multiple enabling technologies, one or more trait technologies, and proprietary germplasm. This is one of the challenges of understanding IP constraints and developing FTO strategies in plant biotechnology where multiple complementary technologies are necessarily integrated to develop new crop varieties.

Strategies for Access to Technologies for Agricultural Research

The complex IP environment surrounding agricultural biotechnology research and development, exemplified by even a relatively simple FTO opinion, has spawned some new strategies and organizations committed to lower the IP barriers to new crop developments and provide more open access to patented technologies. These issues are critical for small private companies attempting to enter this sector but can also be important for public or not-for-profit research institutions. For example, a Federal Circuit Court of Appeals ruling in the Madey v. Duke case emphasized that academic research is not protected by an 'experimental use' exception from patent infringement, even when the research is purely fundamental (Eisenberg, 2003). Most plant biotechnology laboratories routinely use patented technologies in their research without permissions. Although patent owners have rarely been concerned about academic research infringement in agriculture, there are many examples where fundamental biomedical research has been challenged because of IP issues (Marshall, 2002). In addition to IP considerations in basic research, projects carried out in public or not-for-profit institutions that are targeted toward the development of crops for developing country farmers must consider the IP inputs to the project.

Most researchers are still relatively unfamiliar with how to find, understand, and utilize IP information, including published patents and patent applications. In addition, the ability to obtain the rights to use patented technologies has remained uncertain even for projects that have little commercial importance but, for example, may have large impacts in developing country agriculture. Several organizations have now emerged to address the relative inaccessibility of IP information and to provide a framework to ensure that IP does not block applications of agricultural biotechnology and, in particular, to facilitate projects that can have broad humanitarian benefits.

Several public sector and not-for-profit agricultural research institutions, including the University of California, the Donald

Danforth Plant Science Center, North Carolina State University, The Ohio State University, Boyce Thompson Institute for Plant Research, Michigan State University, Cornell University, the University of Wisconsin–Madison, the University of Florida, the USDA, Rutgers University, Texas A&M University, and Purdue University, developed the Public Sector IP Resource for Agriculture (PIPRA). These institutions made a public commitment to participate and promote strategies to collectively manage public sector IP in support of both United States and developing country agriculture (Atkinson *et al.*, 2003). This initial founding group of PIPRA members has grown to more than 45 institutional members in 13 countries, illustrating the widespread concern and interest in working collectively to remove and avoid IP barriers that might slow development of new crops.

A number of strategies have been implemented to enhance FTO using public sector IP for agricultural biotechnology projects. For example, informed decisions regarding dissemination of new knowledge via open publication or protecting it with a patent are clearly important and FTO can be improved if public sector institutions systematically consider how, when, and if to use the patent system to support broad innovation (Boettiger and Chi-Ham, 2007). Even when using the patent system, PIPRA encourages its members to reserve rights to use their newest and best technologies for humanitarian purposes, particularly when they issue exclusive commercial licenses (Bennett, 2007). For US agriculture, it is also important to retain rights to use patented technologies in development of small specialty crops that are not currently within the commercial interests of large private sector companies. The anticipated benefits of a collective IP management regime are to enable an effective assessment of FTO issues, to overcome the fragmentation of public sector IPR and reestablish the necessary FTO in agricultural biotechnology for the public good, and to enhance private sector interactions by more efficiently identifying collective commercial licensing opportunities.

In addition to PIPRA's core activities in developing a clearinghouse of public IP information and analytical resources, PIPRA is developing consolidated technology packages, or patent pools, particularly in the area of enabling technologies for plant transformation. Patent pools have been used effectively by companies to expedite the development and diffusion of innovations that draw on many complementary technology components protected by multiple patents, which are owned by multiple technology developers. In PIPRA's case, the development of a patent pool that provides FTO for plant transformation, which incorporates patented technologies from multiple owners was facilitated by its broad membership and their shared commitment to make these technologies widely available. This strategy is likely to create commercial licensing opportunities as well to support humanitarian projects.

Other initiatives have been established to manage IP issues and facilitate access to technologies in the agricultural and livestock areas, CAMBIA, the African Agricultural Technology Foundation (AATF), and the Global Alliance for Livestock Veterinary Medicines (GALVmed). CAMBIA was modeled after the 'open source' approach that is well developed in the IT software sector. This initiative was named Biological Innovation for Open Society or BiOS and is built on a broad philosophical foundation "to democratize problem solving to enable diverse solutions to problems through decentralized innovation." At the heart of BiOS was licensing language designed to preserve a pool of patented technologies from private appropriation. The idea was to create a 'protected commons' of enabling agricultural biotechnologies that are made freely available and whose use cannot be restricted by third-party patent rights. Even when a patent is granted on a new technology and broadly licensed, accessibility and utility could be reduced as subsequent patents stake proprietary claims for specific uses of the technology or combinations of the technology with other technologies (these are often called improvement patents). By signing the BiOS license, a researcher or an institution agrees to contribute back to the pool, for free distribution, data on the use of the technology and the patent rights to any improvements made to the technology. Over time, based on the improvements invented and contributed back to the pool by a set of researchers, the pool grows. CAMBIA abandoned the BiOs model and adopted a new technology access strategy whereby it abandoned its patent and tangible property rights.

GALVmed is a nonprofit global alliance for the development of livestock vaccines to improve livelihood in developing countries. Their IP asset management strategy anticipates and mitigates IP risks throughout the value chain for the development of livestock health products (Geoola and Boettiger, 2012). Similarly, AATF has implemented a public–private partnership model to access and deliver proprietary agricultural technology to smallholder farmers in Africa. Although many of the technologies are not patented in sub-Saharan Africa, AATF's model recognizes the value in know-how and strategic partnership. In 2008, AATF launched an ambitious initiative to develop Water Use Efficient Maize (WEMA). WEMA is a public–private partnership funded by the Bill and Melinda Gates Foundation, the Howard G. Buffett Foundation, and the USAID. WEMA's key partners include the National Agricultural Research Institutes in Kenya, Mozambique, South Africa, Tanzania, and Uganda; the International Maize and Wheat Improvement Center; and Monsanto. In terms of IP, Monsanto contributed commercial drought-tolerant and insect protection traits on a royalty-free basis and technical expertise.

Conclusions

IP as a tool to foster innovation has been important for hundreds of years but has become a much more prominent feature of research in the life sciences and in agricultural biotechnology in particular in just the past 25 years. This trend is unlikely to be reversed and, indeed, the importance of IP as an intangible asset contributing to the value of life science companies continues to increase. However, robust and sustained innovation in agricultural biotechnology, as in many technology sectors, requires a balance of both exclusive and nonexclusive access to proprietary technologies. This balance should ensure that the fundamental research tools are broadly available to support research and development in many application areas and at the same time provide the exclusivity to

specific trait or trait–crop combinations that will allow the developer of new varieties to recoup their substantial investment. The public sector has a role to play alongside agricultural biotechnology companies, particularly in providing research tools and broad enabling technologies and in addressing biotechnology applications in specialty crops whose market size may not justify commercial investment. The most powerful approaches, however, will come from public–private partnerships that mobilize proprietary technologies to address agricultural biotechnology product developments, which have a high social but low commercial value, including strategies to feed some of the world's poorest populations.

International and Regional Institutions and Instruments for Agricultural Policy, Research, and Development

S Pandey, Gurgaon, Haryana, India

© 2014 Elsevier Inc. All rights reserved.

Glossary

Consultative Group of International Agricultural Research (CGIAR) A consortium of 15 centers that generate and disseminate knowledge, technologies, and policies for agricultural development in order to reduce rural poverty, increase food security, and improve human health and nutrition.

Food security Food security exists when all people, at all times, have physical, social, and economic access to sufficient safe and nutritious food that meets their dietary needs and food preferences for an active and healthy life.

Genetic resources Genetic material (any material of plant, animal, microbial, or other origin containing functional units of heredity) of actual or potential value.

International Agricultural Research Centers (IARCs) They include the CGAIR Centers, and some other institutions which engage in research and development activities for benefit of a region or the world. IARCs receive their funding from governments, philanthropies, and private sources, and their products and services generally are of the global public goods in nature.

International instruments These are treaties, conventions, and agreements among nations for development and implementation of legally binding or voluntary codes of conduct, norms, procedures, or standards.

Regional and international institutions and organizations facilitate cooperation and collaboration among nations, so that they can more efficiently meet the needs of their people provided by the agricultural sector. Exchange of knowledge, experiences, technologies, and products saves them valuable time and resources in facing the challenges to food security and environmental degradation. In a recent exercise, the Food and Agriculture Organization (FAO) of the United Nations, without claiming to be exhaustive, identified 62 instruments it supports related to agricultural production arena alone. Such instruments and organizations differ in their mandates and capacities – some are global and some are regional in their mandates; some focus on policy development and implementation and some on research or technology generation; and some set standards related to food quality and safety and some facilitate trade of agricultural products, etc. The following is a brief description of some relatively more widely known instruments and institutions selected to reflect this diversity in their mandates and functions.

Major International Research and Policy Institutions and Instruments

Food and Agriculture Organization of the United Nations

In 1943, 44 countries agreed to establish a permanent organization of food and agriculture that held its first conference as a specialized agency of the United Nations in 1945. The initial mandate of the FAO was to 'raise levels of nutrition and standards of living of the people under their respective jurisdictions; secure improvements in the efficiency of production and distribution of all food and agricultural products; better the condition of rural populations; and thus contributing toward an expanding world economy and ensuring humanity's freedom from hunger.' An Independent External Evaluation of the FAO in 2007 essentially confirmed the relevance of these goals for the FAO and recommended 'Reform with Growth' for it to continue to deliver its services to members. Today, the FAO's mandate continues to be 'to raise levels of nutrition, improve agricultural productivity, better the lives of rural populations, and contribute to the growth of the world economy.'

In 2011, the FAO's membership constituted 191 countries, 2 associate members, and the European Union. FAO Members meet every 2 years at their conference to 'review global policy issues and international frameworks, as well as to evaluate the work carried out and to approve the budget for the next biennium.' Supervision of technical and budgetary activities of the organization is carried by a council elected by the conference, with assistance from its Program and Finance Committees.

With its headquarters in Rome, 74 country offices, 5 regional and 11 subregional offices, the FAO was present in 130 countries. In April 2011, 53% of its 1835 professional and 1856 support service staff were based in Rome. The FAO serves its members through six technical departments: Agriculture and Consumer Protection, Economics and Social Development, Fisheries and Aquaculture, Forestry, Natural Resource Management and Environment, and Technical Cooperation. The FAO provides its members independent and reliable technical information, a forum to meet and discuss critical issues, policy expertise, and field projects that take technical knowledge to farmers' fields. It hosts a number of international instruments and agreements relevant to agriculture, including International Plant Protection Convention (IPPC), International Treaty on Plant Genetic Resources for Food and Agriculture (ITPGRFA), Agreement for the Establishment of

 doi:10.1016/B978-0-444-52512-3.00041-3

the Regional Commission for Fisheries, and Convention Placing the International Poplar Commission within the framework of FAO.

International Agricultural Research Centers

Among the first International Agricultural Research Centers (IARCs) that specialized on crops important to food security were the International Rice Research Institute (IRRI) established in 1960 in the Philippines and the International Maize and Wheat Improvement Center (CIMMYT) established in 1966 in Mexico. Both centers were largely funded by the Rockefeller and the Ford Foundations and their contributions to the Green Revolution in the Indian subcontinent in the 1960s led to the creation of the Consultative Group on International Agricultural Research (CGIAR) in 1971. In turn, this led, by the turn of the century, to the establishment of 16 independent centers working on technologies and policies relevant to improvement and utilization of crops, livestock, forests, and fisheries.

The reform of the CGIAR in 2008 has led to creation of a consortium that now hosts 15 independent IARCs that conduct their research and development activities with other public, private, and nongovernmental organizations around the world. Establishment of a funding mechanism through CGIAR Fund improves dialog and collaboration among Centers to focus on important goals. The 15 CGIAR Centers are:

Africa Center: A pan-African rice research organization that conducts research and development activities for increasing rice productivity and profitability in a sustainable manner;

Bioversity International: An organization with a global focus that 'places the use and conservation of biodiversity in smallholder farming systems at the center of its work';

Center for International Forestry Research: An organization with a global focus, whose research 'enables more informed and equitable decision making about the use and management of forests in less-developed countries';

International Center for Agricultural Research in the Dry Areas: Conducts research on major food crops for nontropical dry areas in developing countries in order to improve food security and livelihoods of rural poor;

International Center for Tropical Agriculture: Focuses its research to generate knowledge on beans, cassava, and tropical forages in order to improve crop production, income, and natural resource management, especially in smallholder systems;

International Crops Research Institute for Semiarid Tropics: Focusing its research on chickpea, pigeon pea, sorghum, groundnut, and pearl millet in order to generate knowledge for farmers in the semiarid and arid tropical regions of the world;

International Food Policy Research Institute: 'Identifies national and international policies and strategies for meeting the food needs of the developing world on a sustainable basis';

International Institute of Tropical Agriculture: Works especially to address the needs of poor in the tropics through knowledge to 'enhance crop quality and productivity, reduce risk to producers and consumers, and generate wealth from agriculture';

International Livestock Research Institute: Conducts research that 'helps people in developing countries to keep their farm animals alive and productive, increase and sustain their livestock and farm productivity, find profitable markets for their animal products, and reduce their risk to livestock-related diseases';

CIMMYT: Conducts research 'to sustainably increase productivity of maize and wheat systems and thus secure global food security and reduce poverty';

International Potato Center: A global center that 'seeks to achieve food security, increased well-being, gender equity for poor people in root and tuber farming, and food systems in the developing world';

IRRI: Develops 'new rice varieties and rice crop management techniques that help rice farmers to improve the yield and quality of their rice in an environmentally sustainable way';

International Water Management Institute: Works 'to improve the management of land and water resources for food, livelihoods, and the environment' in order to help the poor in developing countries;

World Agroforestry Center: Generates and applies 'the best available knowledge to stimulate agricultural growth, raise farmers' incomes, and protect the environment'; and

World Fish Center: Works to improve livelihoods of poor who depend on fisheries and aquaculture and 'to achieve large-scale, environmentally sustainable increases in supply and access to fish at affordable prices for poor consumers in developing countries.'

There are a few other IARCs such as the World Vegetable Center and the International Fertilizer Development Center that are not a part of CGIAR but operate along the same principles as the CGIAR.

Committee on World Food Security

The Committee on World Food Security (CFS) was established by the FAO Conference in 1975 as a Committee of FAO Council in response to the food crises of the 1970s. 'It is the United Nation's forum for reviewing and following up on policies concerning world food security.' It currently has 123 members, who meet twice during even years. Its terms of reference include:

- Coordination of food security issues at the global level by providing a forum for discussion and coordination of action among public, private, nongovernmental, and other organizations dealing with food security issues,
- Promote greater policy convergence and coordination by developing and adhering to guidelines on food security and promotion of best practices and lessons learned by its members,
- Support and advice to countries and regions for the elimination of hunger, achievement of food security, and application of Voluntary Guidelines for the Right to Food.

The CFS is currently undergoing reform and the reformed CFS will reinforce the above actions and also develop a Global Strategic Framework for Food Security and Nutrition to promote coordination and synergistic actions.

International Plant Protection Convention

IPPC was established almost 60 years ago and now has 177 signatories (members). IPPC 'aims to protect cultivated and wild plants by preventing the introduction and spread of pests.' Its secretariat is provided and hosted by FAO in Rome. The governing body of IPPC is the Commission on Phytosanitary Measures (CPM) that facilitates cooperation among its members. CPM is assisted by a Standards Committee and a Subsidiary Body on Dispute Settlement. Major activities of IPPC include setting international standards on phytosanitary measures, build member capacity to set and implement the standards, and assist countries in assessing their plant protection activities and needs. The work of IPPC is also complemented by several regional plant protection organizations. An independent evaluation of IPPC in 2005–06 highlighted the importance of the Convention and recommended that it pay greater attention to the needs of its developing country members, so that they can better participate in the process of setting international standards and benefit from implementing them.

Commission on Genetic Resources for Food and Agriculture

Commission on Genetic Resources for Food and Agriculture was established by the FAO Council in 1983 at the request of the FAO Conference. It is mandated to cover policies and technologies dealing with conservation and sustainable use of all components of biodiversity dealing with food and agriculture. The Commission's terms of reference are as follows and its 173 members meet once every 2 years:

- To keep under continuous review all the FAO activities related to conservation and sustainable use of genetic resources for food and agriculture and keep the Director-General and relevant FAO Committees informed about them;
- To ensure development of appropriate global systems for genetic resources for food and agriculture in harmony with Convention on Biological Diversity and other such instruments;
- To provide an intergovernmental forum for negotiation of issues dealing with genetic resources for food and agriculture;
- To facilitate and oversee cooperation and coordination with other international bodies dealing with conservation and sustainable use of genetic resources for food and agriculture.

International Treaty on Plant Genetic Resources for Food and Agriculture

In 2001, the FAO members approved establishment of the ITPGRFA which was brought into force in 2004 to support 'conservation and sustainable use of plant genetic resources for food and agriculture and the fair and equitable sharing of the benefits arising out of their use, in harmony with the Convention on Biological Diversity, for sustainable agriculture and food security.' The birth of the Treaty was due to recognition among the FAO members that no country was self-sufficient in its own plant genetic resources to meet its food, feed, and other needs, and they all depended on each other for them. The Treaty also aimed at keeping much of the world's plant genetic resources in the public domain. The Treaty also recognizes the role farmers have played in conserving and improving the plant genetic resources for food and agriculture while also utilizing it. It has a fast-growing number of contracting parties, which stood at approximately 130 in 2012. The contracting parties of the Treaty constitute its Governing Body, whose 'basic function is to promote the full implementation of the Treaty, including the provision of policy guidance on the implementation of the Treaty.' The governing body of the Treaty meets once every 2 years. Much of the plant genetic resources currently listed under the mandate of the Treaty come from CGIAR centers; however, increasingly, other contracting parties are also including their germplasm under the Treaty.

International Rice Commission

The International Rice Commission (IRC) was established by the FAO members in 1949 'in order to promote national and international action in matters relating to the production, conservation, distribution, and consumption of rice.' At present, IRC has 62 members including most rice-growing countries as well as some nonrice producers. Its activities include analysis and provision of rice-related information, recommend national and international actions related to sustainable intensification of rice production, and organization of regular sessions of IRC in order to discuss recent developments in science and policy issues and challenges affecting rice production, distribution, and consumption. In recent years, interest in IRC has waned with the emergence of alternate providers of some of its services. However, an effort is underway by members to reevaluate its future, given the status of rice as the world's number one food, and its relevance to climate change adaptation and mitigation. An independent international forum may be necessary to provide countries an opportunity to discuss issues of global importance in relation to rice.

Rotterdam Convention on Prior Informed Consent Procedure

Rotterdam Convention on Prior Informed Consent (PIC) Procedure for certain hazardous Chemicals and Pesticides in international trade was adopted in 1998 and came into force in 2004 'to promote shared responsibility and cooperative efforts among parties in the international trade of certain hazardous chemicals in order to protect human health and the environment from potential harm; and to contribute to the environmentally sound use of those hazardous chemicals, by facilitating information exchange about their characteristics, by providing for a national decision-making process on their import and export, and by disseminating these decisions to parties.' It creates 'legally binding obligations for the implementation of the PIC procedure.' It currently has 149 Parties. The Annex III of the Convention lists 43 chemicals, of which 32 are pesticides and 11 are industrial chemicals. The secretariat of the Convention is currently jointly provided by

the FAO (for pesticides) and United Nations Environment Programme (for industrial chemicals).

Major Regional Organizations

Some research and collaboration organizations and institutions have emerged in different regions that promote cooperation among members. They normally operate on funds received from assessed contributions from their membership and on additional donor support for specific activities and projects. As member countries are from a region, they have greater similarities in their natural resource and ecological, social, and cultural assets and values, making cooperation easier and more rewarding. The following are examples of such institutions/organizations.

Inter-American Institute for Cooperation on Agriculture

Founded in 1942 and with its headquarters in San Jose, Costa Rica, the Inter-American Institute for Cooperation on Agriculture (IICA) is the 'specialized agency of the Inter-American System for promotion of agriculture and rural well-being' and 'making agriculture competitive and sustainable in the Americas.' With its offices in each of the 34 member countries, the institute works on meeting the needs of its member countries in areas such as 'technological innovation, agricultural health and food safety, agribusiness and commercialization, territorial management and rural well-being, food security, natural resources, and climate change.' More specifically, the institute focuses on (1) Designing, analysis, and evaluation of public policies and strategies; (2) Strengthening and modernizing institutions; (3) Capacity building; (4) Knowledge management for agriculture and rural well-being; and (5) Supporting countries on specific issues and investment projects.

New Partnership for Africa's Development/Comprehensive Africa Agriculture Development Programme

The Comprehensive Africa Agriculture Development Programme (CAADP) is an initiative of the New Partnership for Africa's Development (NEPAD) to eliminate hunger and reduce poverty in Africa through agriculture. This is an Africa-led and Africa-owned initiative that enjoys broad international support. It has four pillars: (1) Land and water management that aims to 'extend the area under sustainable land management and reliable water control systems.' Three initiatives under this pillar include TerrAfrica (addresses land degradation issues across the region through coordinated action); conservation agriculture (a Norway-funded program of countries and the FAO to improve soil health, promote water use efficiency, and lower the cost of production); and water and irrigation (to improve irrigation infrastructure in the region). (2) Market access that aims to 'increase market access through improved infrastructure and other trade-related interventions.' Major issues addressed include transportation, storage and packaging, retail facilities, information, and supply chains. (3) Food supply and hunger 'aims to increase food supply and reduce hunger across the region by raising smallholder productivity and improving responses to food emergencies.' The work under this pillar directly relates to the first Millennium Development Goal (MDG-1) as it focuses on chronically food insecure and vulnerable populations. The major thrust is on increasing domestic food production and marketing capacity, building trade, and improving household income. (4) Agricultural research aims to 'improve agricultural research and systems in order to disseminate appropriate new technologies.' Major focus is on improving relevance and effectiveness of agricultural research conducted by countries, Conseil pour la Recherche Agricoles en Afrique in West Africa, and the Association for Strengthening Agricultural Research in East and Central Africa, as well as others operating in the region.

Forum for Agricultural Research in Africa

The Forum for Agricultural Research in Africa (FARA) forms a coalition of national, regional, and international agricultural organizations working in Africa in order to 'sustainably reduce African food insecurity and poverty and enhance environmental conditions.' It aims to specifically achieve broad-based agricultural productivity, competitiveness, and market sustainability. It delivers its results through four networking support functions, viz., advocacy and policy, access to knowledge and technologies, capacity strengthening, and partnerships and strategic alliances. The FARA is governed by a general assembly that sets its overall vision and direction. An elected executive committee supervises the work of its secretariat.

Conclusions and the Future

International instruments and institutions have played a significant role in feeding the world over the years. Their impact varies with the clarity of their mandate, the vision and determination of their members in ensuring that they play their role, and the availability of financial support. Recent critical independent evaluations of some of these instruments and institutions (e.g., the FAO, CGIAR, and IPPC) have affirmed their importance to global food security and trade and made critical suggestions for their continued relevance and effectiveness. They have emphasized the need for instruments and institutions to work more closely to serve their members as well as to improve their efficiency. They have also urged their members and the donor community to provide additional financial resources and guidance so that the institutions and instruments can play the roles mandated to them. There have been suggestions that perhaps there are already too many instruments and institutions and some of them have lost their relevance and are overly bureaucratic; however, new ones will continue to emerge depending on the needs perceived by countries and their politics. In the future, it may be well worth examining the roles, functioning, and efficiency of the existing institutions and instruments, and appropriately assigning emerging new needed roles to them, before developing additional ones.

Glossary

Antidumping duty A tariff levied against a country that is dumping.
Countervailing duty Tariff imposed by the importing country in response to export dumping by exporters (i.e., the exporter either sells below cost of production or sells abroad at a price below that charged in the home market).
Gains from trade The net benefits to agents from allowing an increase in voluntary trading with each other.
Import quota Specifies the maximum amount of a good that can be imported per year.
Optimal revenue tariff Set by the government to maximize government tariff revenue from imports; this tariff has the effect of restricting trade even more than for the optimal large country tariff.
Optimal welfare tariff One that is set by the government to maximize a large country's total welfare.
Scientific tariff One that raises the price of an imported good to the level of the domestic price, so as to leave domestic producers unaffected.
Tariff Policy instrument that drive a price wedge between what the exporters receive and what the importer pays.
Tariff rate quota A combination of an import tariff and an import quota in which imports below a specified quantity enter at a low tariff or nonexistent level and imports above that quantity enter at a higher tariff.
Voluntary export restraint A restriction on a country's imports that is achieved by negotiating with the foreign exporting country for it to restrict its exports. In some cases, a voluntary export restraint can actually increase the welfare of foreign producers.

Introduction

Tariffs on agricultural traded goods are widespread worldwide. From theory and empirical evidence, one can deduce why certain producers and other special interest groups lobby for tariffs.

> Almost every nation protects its industries from foreign competition. One such protectionist instrument is the tariff. This is an instrument used by importers of a specific commodity; it drives a wedge between export and import prices. For example, if a country imposes a dollar per pound tariff on beef imports, excluding all other factors such as transportation costs, the price in the exporting nation is one dollar below the price producers receive in the importing country. (Schmitz and Schmitz, 1994, p. 269).

First, the theory of tariffs is explored and the empirical data relating to their importance is examined. For many years, global agricultural trade negotiations under both the General Agreement on Tariffs and Trade and the World Trade Organization (WTO) have been stalled because of tariffs.

Import Tariffs

A common trade barrier is the import tariff (e.g., Canadian tariffs on dairy products and US tariffs on beef imports). Import tariffs are a way for governments to protect their domestic industries (Josling *et al.*, 2010). Two of the most common types of tariffs are: (1) a specific tariff based on per unit cost and (2) an *ad valorem* tariff based on a percentage of the price of the product.

There is a rich history on the use of tariffs (Schmitz *et al.*, 2002). In the United States, for example, tariffs of 5% were established as early as 1789. In 1816, US tariffs were increased to between 15% and 20%. After 1870, the sentiment for tariff reform in the United States grew rapidly. The Dawes Bill of 1872 lowered tariffs by 10%; however, the see-saw approach to tariffs gave rise to the McKinley tariff of 1890, which gave the United States the highest protection afforded by any of the previous tariff acts. After a brief move to lower tariffs in 1913, the United States returned to a protectionist policy in 1921. The most dramatic increase in US tariffs came with the introduction of the Smoot–Hawley Tariff in 1930. Canada immediately responded by placing its own higher tariffs on US imports, which increased Canada's trade with Britain even more than after the well-known removal of the Corn Laws in 1820. Canada remained a significant agricultural exporter to Britain until the end of the Second World War (Marchildon, 1998).

Small Country Tariffs

In Figure 1, the effects of a specific import tariff on different groups, including producers and consumers, are shown. In Figure 1(a), the small-country case, the domestic supply schedule is S, whereas the domestic demand schedule is D. The free trade price is P_w. If tariff T is introduced, the internal price in the small country will increase to P_1 and imports will be reduced to $(Q_2 - Q_1)$. The net loss from the tariff is $(acb + dfe)$. Producers will gain (P_1P_wca), consumers will lose (P_1P_wed), and the government will collect$(abfd)$ in tariff revenue.

Now, consider Figure 1(b), the large-country case. The free trade price P_w is set in the world market where excess supply ES equals excess demand ED_0. Suppose tariff T is again introduced. This tariff will shift the excess demand curve downward

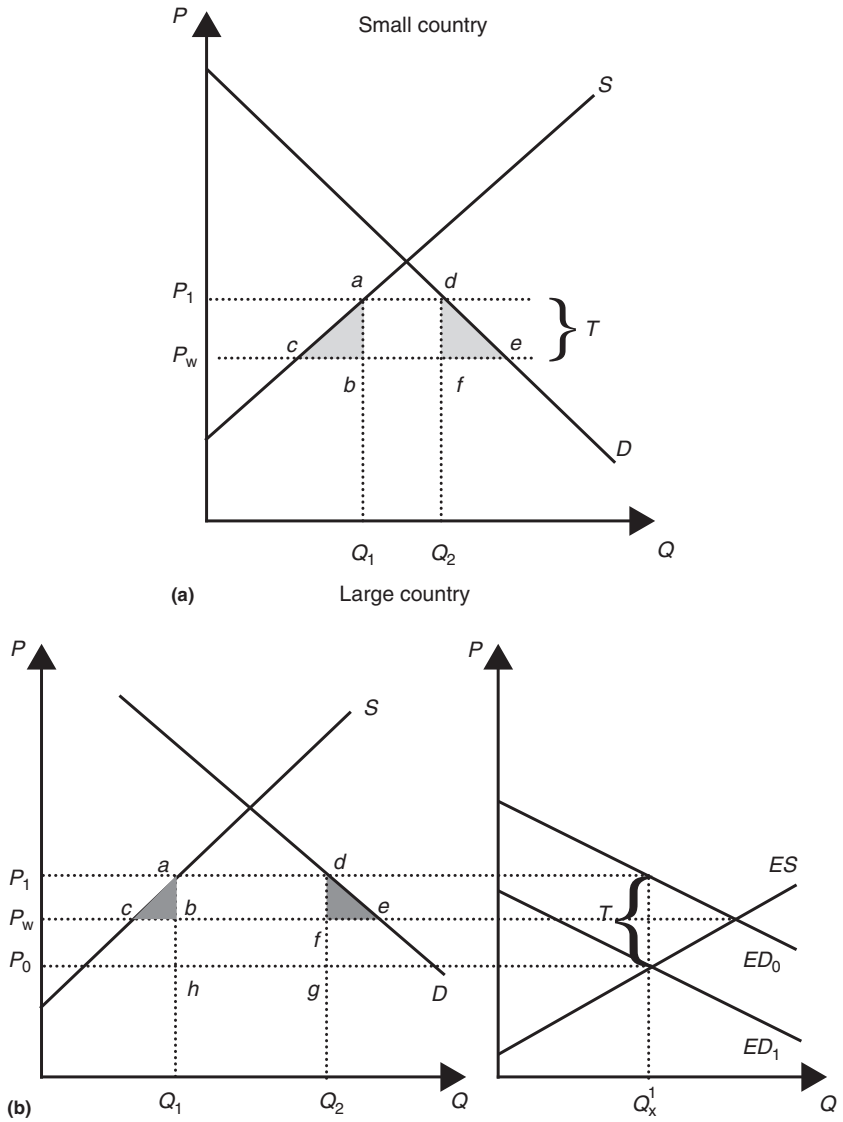

Figure 1 Import tariffs in (a) a small country and (b) a large country. *D*, domestic demand curve; ED_0, initial excess demand curve; ED_1, final excess demand curve; *ES*, excess supply curve; and *S*, domestic supply curve. Reproduced from Schmitz, A., Moss, C.B., Schmitz, T.G., Furtan, H. W., Schmitz, H.C., 2010. Agricultural Policy, Agribusiness, and Rent-Seeking Behaviour, second ed. Toronto: University of Toronto Press.

from ED_0 to ED_1, the internal price will increase to P_1, and the import price (world price) will fall to P_0. In this case, there is a net gain to the large country from the use of a tariff in the amount of $[(bhgf) - (acb + dfe)]$. If $bhgf > (acb + dfe)$, the tariff generates a net gain for the large country; in either case, the exporter loses.

From the above, producers in importing countries always gain from tariffs, and therefore spend considerable sums of money rent-seeking politicians to support tariffs. However, consumers in the importing countries lose from tariffs. As there are typically a large number of consumers and a small number of producers of any specific product, the incentive for an individual producer to lobby the government to increase tariffs on a particular product is much higher than the incentive for an individual consumer to lobby the government to reduce tariffs on that same product. This is the main reason why agricultural producer groups are typically more politically influential than food-related consumer advocate groups.

Optimal Welfare Tariffs

Optimal welfare tariffs have a long history in international economics. The optimal welfare tariff is welfare improving for the importing country, but in aggregate there is a net loss when all countries are taken into account. In Figure 2, the excess supply curve of country A is given by ES_A, and the excess demand curve of country B is ED_B. The free trade price is P_w. The optimal welfare tariff $(P'_B - P'_A)$ is determined where the marginal outlay curve *MO* intersects the excess demand curve ED_B. If country B imposes an optimal import tariff $(P'_B - P'_A)$, it behaves as a monopsonist with respect to country A by

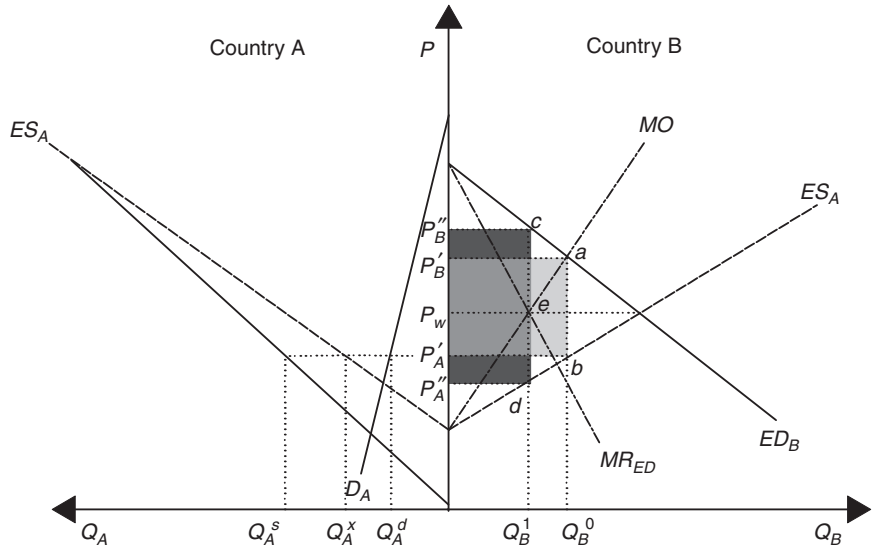

Figure 2 Optimal welfare and revenue tariffs. D_A, domestic demand curve of country A; ED_B, excess demand curve of country B; ES_A, excess supply curve of country A; *MO*, marginal outlay with respect to the excess supply curve of country A; and MR_{ED}, marginal revenue with respect to the excess demand curve of country B. Toronto: University of Toronto Press.

reducing imports to $Q_B{}^0$. The total tariff collected is $(P'_BP'_Aba)$. Consumers lose from the tariff whereas producers gain.

Optimal Revenue Tariffs

Governments use revenue tariffs to collect revenue from imports. These types of tariffs have been used by the Japanese Food Agency and by the European Union (EU) (Carter and Schmitz, 1979; Schmitz *et al.*, 1981). Conceptually, these tariffs are set, so the government can exploit both exporters and domestic consumers. The optimal revenue tariff is determined where *MO* and the marginal revenue to the excess demand curve MR_{ED} intersect (Figure 2). The optimal revenue tariff is $(P''_B - P''_A)$ per unit of import. The tariff revenue collected is $(P''_BP''_Adc)$. Note that imports are always lower ($Q_B{}^1$ compared with $Q_B{}^0$) and the tariff revenue is always higher under the optimal revenue tariff when compared with the optimal welfare tariff.

General Equilibrium Tariffs

Figure 3 shows the effects of tariffs for more than one country. The aggregate production possibility for agriculture and manufacturing is represented by X_1X_2. At relative prices (terms of trade) represented by P_1, the output of manufacturing is M, whereas A of agriculture is produced. This is under no trade. At free trade, the relative price is P_2. Output of agriculture increases to $\overline{A}$ but production of manufacturing decreases to $\overline{M}$. Welfare is improved under free trade because consumption occurs at C_2, which is on a higher indifference curve than C_1.

A tariff causes production to fall between the free trade and no trade points. For example, for a tariff that changes the terms of trade to P_3, agricultural output is A_0, and M_0 represents the manufacturing output. The tariff drawn in Figure 3 is welfare improving (C_3 lies above C_2).

In cases where tariffs are welfare improving, the important assumption is that the trading partner does not retaliate. Under extreme retaliation (i.e., retaliatory tariffs), the outcome can be very different as both the countries jointly can lose from tariffs.

Optimal Byrd Tariff

The Continued Dumping and Subsidy Offset Act (CDSOA) attached as an amendment in 2001 by senator Robert Byrd of West Virginia stipulated that the tariff revenue should be reimbursed to the petitioners for the tariff. The Byrd Amendment (which the CDSOA is commonly referred to) provided additional incentives for rent-seeking behavior by special interest groups (Schmitz and Schmitz, 2012); Schmitz *et al.* (2006) derived the optimal Byrd processor tariff in a vertical market structure. They considered a group of processors, referred to as the processing industry, who buy inputs for processing from abroad and from domestic producers. The excess supply curve for the exporter of an input for processing is *ES* (Figure 4). The importer's domestic supply schedule for producing the same input is S_d. The demand curve for the processor's output is D_c. The processor's derived-demand curve for the input is D_d. The free trade price for the input is P_f and exports are Q_f.

Under free trade, the raw-product processor will purchase Q_f from abroad at price P_f and will purchase Q_1 domestically at price P_f. In essence, the processor uses $(Q_f + Q_1)$ inputs so that its total outlay for the raw product is $(P_fQ_f + P_fQ_1)$. A portion of the processed input comes in the form of imports, and the remainder is produced domestically. Under constant processor costs, given the consumer demand for the final product D_c, the processor will produce Q^* and will sell the final product at P^*.

Under the optimal processor tariff $(P_t - P_p)$, the processor now imports only Q_t (which equals Q_x of exports) of the input

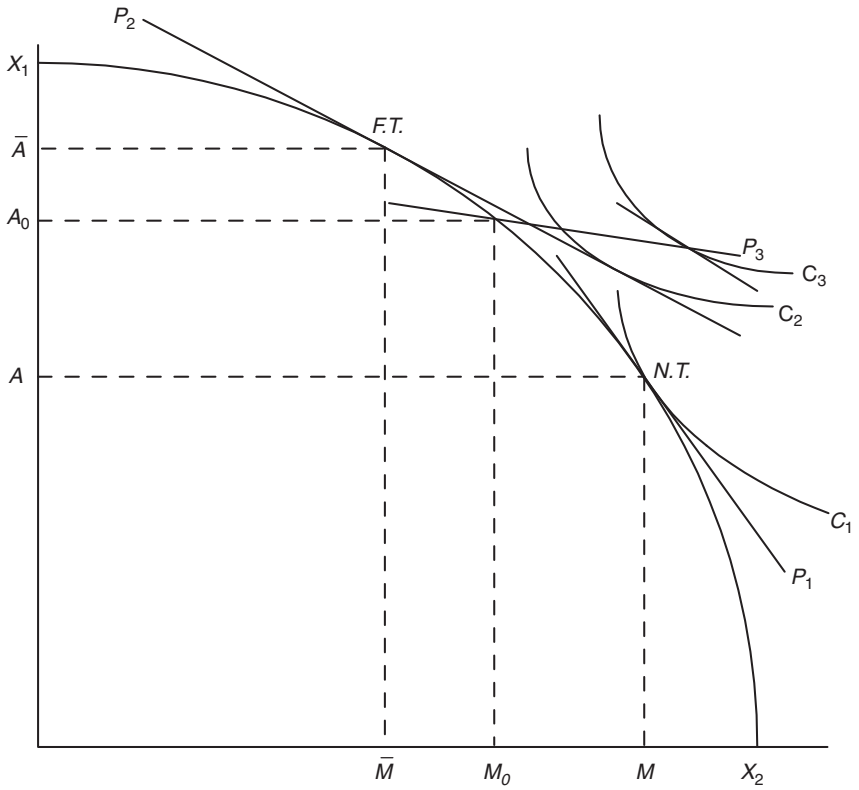

Figure 3 Tarriffs in general equilibrium. (A_0, M_0), amount of X_1 and X_2 consumed in equilibrium under a tariff; $C_{1,2,3}$, community indifference curves; *F.T.*, FREE TRADE equilibrium point where the country consumes A bar of X_1 and M bar of X_2; *N.T.*, NO TRADE equilibrium point where the country consumes A of X_1 and M of X_2; P_1, terms of trade under no trade; P_2, terms of trade under free trade; and P_3, terms of trade under a tariff. Toronto: University of Toronto Press.

to be processed at price P_t. The tariff revenue abP_pP_t will be reimbursed to the processor; hence, its effective outlay on imports is reduced to P_pQ_t. However, raw product processor expenditures on domestic inputs will increase from P_fQ_1 to P_tQ_2. Total expenditures by the processor on purchases of both imports and domestic raw product will actually decrease when the tariff revenue is rebated to the processor. Compared with free trade, the optimal Byrd tariff $(P_t - P_p)$ results in a gain to

both processors (abP_pP_t) and domestic producers (P_tP_fec). (The optimal processor tariff is derived where the marginal outlay curve *MO* intersects the marginal revenue curve *MR* at the excess derived-demand curve *ED* as in **Figure 4**.)

Trade Remedy Actions

The WTO allows for trade remedy actions including antidumping (AD) and countervailing duties (CVDs). AD actions can be imposed when two conditions are met: (1) the US Department of Commerce (USDOC) determines that foreign goods are sold, or likely to be sold at less than fair value (LTFV) and (2) the US International Trade Commission (USITC) determines that an industry in the United States is injured materially, or threatened with injury, from the sale of the goods. Dumping, or sales at LTFV, typically occurs when a company exports a product at a price lower than the price it normally charges in its own home market.

The WTO agreement allows governments to act against dumping when there is genuine material injury. A government must show that dumping is taking place, calculate the extent of dumping (the dumping margin), and show that dumping is causing injury. Typically, an AD action means charging extra import duties in order to bring the price closer to normal value. The dumping margin is the difference between the price or cost in the home market (the normal value) and the price in the export market.

The WTO agreement stipulates three methods for calculating the normal value: (1) a comparison of the export price with the price in the exporter's home market; (2) a comparison of the export price with the price charged in a third-country market; or (3) a calculation based on the combination of the exporter's production costs, other expenses, and normal profit (constructed value).

CVDs can be imposed when (1) the USDOC determines that the government of a country, or any public entity within a country, provides a countervailable subsidy on the manufacture, production, or export of goods sold into the United States, and (2) the USITC determines that an industry in the United States is injured materially or threatened with injury by reason of these imports. The types of subsidies covered by CVD actions are specified in the WTO Agreement on Subsidies and CV Measures (WTO, 2003). Only specific subsidies that apply to a specific enterprise or industry group are usually actionable. The WTO Agreement identifies three types of actionable subsidies: (1) subsidies that provide an advantage over rival exporters in a third-country market, (2) subsidies that advantage the domestic industry over exporters to that country, and (3) subsidies that damage the domestic industry in the importing country.

The Scientific Tariff and Multifunctionality

Tariffs are used to promote noneconomic objectives of various kinds through their influence on domestic production and consumption of certain products (Schmitz and Schmitz, 1994). Examples include tariffs to promote (1) national self-sufficiency and independence, (2) diversification and industrialization, (3) a way of life, (4) military preparedness, (5) bargaining, and (6) food security. Earlier scholars labeled these as scientific tariffs (Johnson, 1960). More recent literature categorizes these under the label of multifunctionality.

Of the tariffs listed above, the most popular one appears to be the tariff that promotes food security. Strong arguments for food security have been made because of world famines that are natural or manmade. However, a word of caution is needed. Much of the literature discredits the notion of scientific tariffs because other policy instruments are often superior to tariffs to achieve specific policy objectives (Schmitz and Moss, 2005).

Tariff Rate Quotas and Importer/Exporter Agreements

Often, protection takes the form of tariffs in conjunction with quotas. For example, the United States restricts sugar imports through a tariff rate quota (TRQ) system. High tariffs are applied to US imports of sugar that exceed the quota-level specification. According to USDA/ERS (2013),

> A TRQ is a two-tiered tariff for which the tariff rate charged depends on the volume of imports. A low-tier (in-quota) tariff is charged on imports without the quota volume. A high-tier (over quota) tariff is charged on imports in excess of the quota volume. Almost all raw cane sugar, refined sugars and sugar syrups, and sugar-containing products are imported under TRQs for those products.

As of 1 January 2008, sugar from Mexico enters the United States duty free under the North American Free Trade Agreement (NAFTA) and is not subject to quota restrictions. Since then, US sugar imports from Mexico have both increased significantly and become more volatile due to weather and other factors.

In agriculture, there are cases where the prices for traded commodities are agreed to by governments. A classic example is the outcome of negotiations between Mexico and the US on trade in tomatoes. In response to years of tariff-related disputes over tomatoes (Bredahl *et al.*, 1987), the two countries agreed in 1996 to a suspension agreement where a minimum price was set below which Mexico could not export tomatoes to the US. This suspension agreement was renewed in 2013.

According to the USDOC (2013),

> On March 4, 2013, the United States Department of Commerce and producers/exporters accounting for substantially all imports of fresh tomatoes from Mexico signed an agreement suspending the antidumping investigation on fresh tomatoes from Mexico. The basis for the agreement was a commitment by each signatory producer/exporter to sell the subject merchandise at or above the reference price, which will eliminate completely the injurious effects of exports of fresh tomatoes to the United States.

These types of agreements often take the form of either a voluntary export restraint on trade shipments or an import/export cartel between the two countries.

Equivalence of Tariffs and Quotas

Agricultural trade is often restricted by both tariffs and nontariff barriers. Consider an import quota. This trade instrument

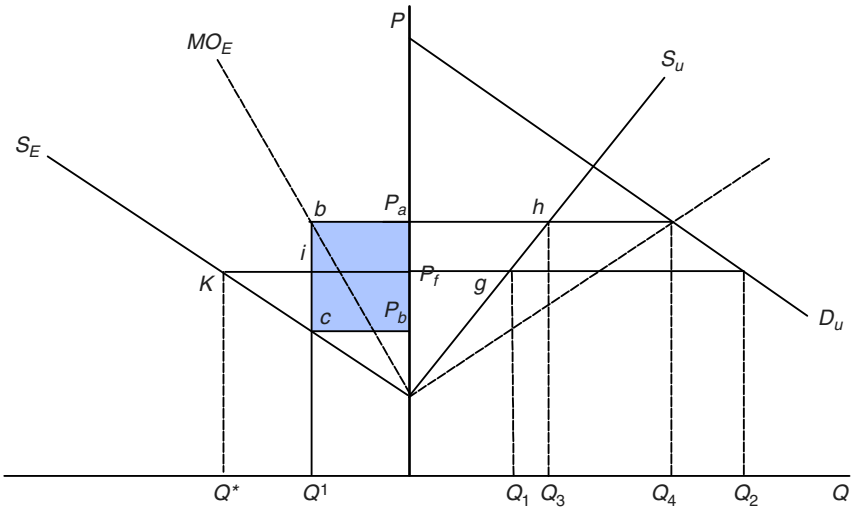

Figure 5 The equivalence between tariffs and quotas. D_u, domestic demand curve for the importing country; MO_E, marginal outlay with respect to the exporter's excess supply curve; S_E, excess supply curve of the exporting country; and S_u, domestic supply curve for the importing country.

can have the same effect on trade flows as can a tariff, but the income distributional effect is very different. Consider Figure 5, where import demand is D_u, import supply is S_u, and export supply is S_E. The free trade price is P_f and imports total (Q_1Q_2). Under an optimal tariff, the import price becomes P_a. Production in the importing country increases from Q_1 to Q_3, and producers gain P_aP_fgh from the tariff. The tariff revenue collected by the government in the importing country totals (bcP_bP_a).

Suppose, instead of a tariff, the importing country imposes a quota in the amount (Q_4-Q_3). The effect on production and trade flows is the same, but note that the government no longer collects the tariff revenue. As a result, there is a net loss from the quota for the importer. However, the exporter can gain from the import quota. Even though the producer price falls to P_b, there is a revenue gain of (bcP_bP_a), which can be larger than the loss from a fall in the price of the export good. On net, the exporter gains, from the import quota, an amount $(biP_fP_a) - (kci)$.

A key element of US sugar policy has been import quotas on sugar from abroad. In certain periods of history, these have resulted in US internal prices for sugar being well above export prices. However, there are preferred sugar exporters who are able to sell sugar to the United States at price P_a, but there are others who sell at prices below the US internal prices to countries not included in demand D_u.

Empirical Work

There are empirical estimates of the impact of agricultural trade barriers. Quite often, however, the estimates are a result of combined policy instruments that include tariffs. Often agricultural policy instruments, such as price supports, are used in conjunction with barriers to trade, such as tariffs (Schmitz and Schmitz, 2012). Moreover, because of retaliatory action by an importer in response to a tariff policy by an exporter, a situation can arise where trade ceases. In addition, under retaliatory action, tariffs can give way to production subsidies. As a result, even if one correctly measures the impact of production subsidies in a trade context, the policy instrument that gives rise to the subsidies can be a tariff.

Overall Agricultural Distortions

Anderson (2009), Anderson and Martin (2009), Anderson and Masters (2009), Anderson and Swinnen (2009), and Anderson and Valdes (2009) give an in-depth analysis of the many agricultural trade and policy distortions that exist worldwide. This work, which includes 75 countries that together account for more than 90% of the world's farmers, concludes that without the agricultural price and trade policy reforms of 2004, global welfare would be lower by US$233 billion annually. Owing to the 2004 reforms, low-income economies have benefited more than high-income economies; the world has moved closer toward global free trade in goods (annual global welfare cost of policies at US$168 billion in 1980, compared with an estimated gain of US$233 billion in 2004); and all high-income economies have lowered price supports for their farmers, with some countries replacing price supports with assistance partially decoupled from production. Their work is consistent with the authors' earlier finding (Schmitz *et al.*, 1997) that the gains from trade can be negative even though the volume of trade can be large. Quite often, the welfare impact from removing government domestic policy distortions far outweighs the classic gains from trade.

Case Studies

Tomatoes

For many years, the United States attempted to restrict tomato imports from Mexico through the use of import tariffs, but on many occasions failed. Bredahl *et al.* (1987) demonstrated that the imposition of tariffs is a competitive strategy, as producers on both sides of the border cannot gain from tariffs. They demonstrated two alternative strategies where gains are possible: (1) voluntary export restraints or (2) an import–export

cartel on tomatoes. Interestingly, the United States gave up on the strategy to impose tariffs, and instead agreed with Mexico on a suspension agreement. The first suspension agreement was put in place in 1996 and was replaced with a new agreement in 2013. Little analysis has been done on the impact of this agreement, both in terms of its effect on US and Mexican producers and consumers.

The cotton controversy

In an ongoing trade dispute that was a major reason for the breakdown of the Doha Round of WTO trade negotiations in Cancun in September 2003, Brazil challenged the United States on the use of cotton subsidies that allegedly interfere with cotton exports from Brazil. Schmitz *et al.* (2007) estimate that US cotton policy lowered world cotton prices by 10–15%. Brazil won part of its case against US cotton subsidies in 2003. As of 2013, the United States continues to make payments to Brazil of approximately US$100 million per year. This is likely to continue as in June 2013 the price of cotton dropped below the US$71.25 cents per pound target price. The same issue revolves around sugar. Brazil sued Europe over EU sugar policy (Powell and Schmitz, 2005) and forced Europe to lower its sugar subsidies. This takes on added interest in view of the 2013 trade talks between the EU and the US over further trade liberalization.

Ethanol tariffs

The United States launched several controversial programs to promote the conversion of corn into ethanol. In the 1980s, a 54-cents-per-gallon tariff was imposed on imports. In 2004, US blenders of transportation fuel received a tax credit of 46 cents per gallon. The trade barrier and subsidy were the source of an ongoing ethanol dispute between the US (a country that produces ethanol from corn) and Brazil (a country that produces ethanol from sugarcane). On 31 December 2011 both the tariff and the tax credit were removed and these changes complemented the tariff elimination enacted by Brazil in 2010. The US program changed from the government providing subsidies to ethanol processors to a blend ethanol/gasoline ratio requirement (de Gorter and Just, 2009; Just and de Gorter, 2009). It remains to be seen whether or not the US can satisfy its ethanol mandate in the absence of the subsidies but there is evidence that recently, Brazil and the US have begun collaborating in an effort to promote the global use of not just ethanol, but also biofuels in general.

US shrimp imports from China

According to Adams *et al.* (2005), p. 225,

> The warm-water shrimp-harvesting industry in the Gulf of Mexico and South Atlantic (GSA) region represents the most economically important component of all the domestic commercial seafood-harvesting sectors in the United States.

Since 1975, shrimp harvesters in the GSA region have sought regulatory relief from imports on several occasions. Examples include:

1. In 1975, the USITC responded to the International Shrimp Congress, which led to adjustment assistance permitted under Title II of the Trade Act of 1974.
2. US Senator Breaux authored a bill to formulate a policy to provide for domestic shrimp industry protection. A temporary 5-year import quota combined with a 30% *ad valorem* tariff was proposed. The bill failed.
3. In 1985, the USITC responded to public hearings on imposing trade restrictions on shrimp imports, but did not take any concrete action (USITC, 1994).

US imports of garlic from China

China is one of the world's leading producers of garlic, a product used for cooking and medicinal purposes. In 1994, the Fresh Garlic Producers Association of the United States alleged that fresh garlic from China was being imported to the US market at LTFV. The USITC ruled in favor of the United States in the garlic AD case (Yamazaki and Paggi, 2005). Three 5-year reviews have been initiated by the USITC since 1999 to examine whether the AD duties should be revoked. They continue to conclude that its removal would likely lead to the continuation or recurrence of the material injury to the US domestic garlic industry and, in April 2012, the United States announced that it would maintain the existing AD duty on fresh garlic from China. The duty margin is set at 376.67%.

United States sugar disputes with Mexico and the European Union

For years, the United States restricted imports of sugar from Mexico by imposing an import quota. However, with the passage of NAFTA in 1994, the US converted the import quota into a TRQ and agreed to phase out the over quota tariff over a 15-year period. During the period that the US restricted sugar imports from Mexico there were several retaliatory policies implemented by Mexico. For example, in 2002, the Mexican government imposed a 20% 'soda tax' on all beverages sold in Mexico that were not sweetened with its own cane sugar. This effectively eliminated the use of US high fructose corn syrup in Mexican soda production. The WTO ruled in favor of the US and Mexico eliminated the tax in 2007. Mexico also imposed other retaliatory duties to support freer trade during this time.

In 2008, free trade in sweeteners between the US and Mexico began. As a result, US sugar imports from Mexico increased from 0.054 million metric tons (mmt) in 2005–06 to 0.63 mmt in 2006–07 to 1.27 mmt in 2008–09. In general, US sugar imports from Mexico increased significantly after 2007 but also became much more volatile, reaching a low of 732 000 mt in 2009–10 and a high of 1.55 million mt in 2010–11.

The EU, historically, has provided the highest support for sugar producers. High price supports were accompanied by sugar export subsidies. In an interesting case in 2004, Brazil launched a WTO investigation against the EU sugar regime. The WTO supported Brazil's case, with several actions being taken by the EU to deal with Brazil's concerns (Powell and Schmitz, 2005).

The beef dispute between the United States and Canada

In 1999, the Rancher-Cattlemen Action Legal Foundation (R-CALF) filed an AD petition with the USITC alleging that Canada was dumping live cattle onto the US market. The USITC ruled in Canada's favor that live cattle from Canada were not being dumped on the US market. In addition, R-CALF filed a CV complaint against the Canadian cattle industry, contending that

Canadian cattle were being fed cheap barley subsidized by the Canadian Wheat Board. Again, the USITC ruled in Canada's favor. The defense argued that neither case had an economic or empirical base (Wohlgenant and Schmitz, 2005). As a result, USITC ruled in favor of the Canadian cattle industry. However, the USDOC sided with R-CALF and imposed temporary duties on Canada (Schmitz *et al.*, 2005).

Conclusions

Trade distortions that include tariffs have declined significantly since the early classic written by Johnson (1973) titled 'Agriculture in Disarray.' As emphasized, there are many trade barrier instruments, including tariffs, and the empirical evidence presented above includes the effect of removing several trade instruments at the same time. Even so, the increased liberalization, because of removing trade barriers, is significantly impacted by the tariff component of trade distorting policy instruments.

The effects of a country's retaliatory use of CV and AD duties have been discussed. However, over time, lowering or removing tariffs that exist may have little to do with retaliatory actions by importers under either AD or CVD legislation.

Glossary

Ballast water Water carried in tanks on ships in order to maintain ship stability during voyages.
Ballast water exchange Replacing coastal water with ocean water during a voyage.
Ecosystem The network of interactions of living organisms as well as the physical and chemical components of their environment within an area than can be defined.
Habitat suitability rating When habitats are compared with a rating model where unsuitable is zero (0.0) and optimum is (1.0) using parameters including water temperature, salinity, gradient, cover, substrate, etc.
Species displacement When a species is replaced by another within a habitat due to space occupation, behavior activity, or other competition.
Subtropical Habitats that are tropical in nature but located above or below the latitudes of tropical environments.
Temperate Characteristic of climate between the tropical and polar latitudes.
Tropical Characteristic of climate between the Tropic of Cancer and the Tropic of Capricorn.
Vector As in dispersal vector, an agent that transports an organism from one place to another.

Introduction

Movement of aquatic animals from their native range into other locations constitutes an invasion, often with damaging consequences in the new location. Humans are responsible for movement of many aquatic animals into new locations. Unintended and negative consequences of their release have occurred in many cases due to species displacement, ecosystem destruction, and sometimes from diseases carried by the invasive aquatic animal. In some instances the potential for using exotic animals as human food or as biological control for other invasive organisms returns economic benefit from the introduction.

The degree of concern about aquatic animal invasions depends on the impact of that species on human activities or ecosystem diversity in the specific area of invasion. The potential for spreading into other locations increases the importance of that species globally. An aquatic species that has spread widely over several centuries can still be invasive even though it may be almost ubiquitous. Recent invaders may be no less important, because of their ability to expand their range quickly and displace less competitive species.

Historic Introductions of Aquatic Species

Aquatic species introductions, leading to invasive spread, may have begun with the common carp, *Cyprinus carpio*. Common carp are presumed to be two subspecies which were documented to live in Europe and Asia more than 10 000 years ago, then domesticated independently (Balon, 1995). Recent genetic evidence confirms the existence of the two subspecies of common carp (Zhou *et al.*, 2003). Domestication involves animal movement and therefore the first spread of invasive common carp may be attributed to the Romans for moving them from the Danube across Europe (Balon, 1995). Now, common carp are one of the most important invasive aquatic animals in the world. More than 3.5 million tonnes of common carp are produced by aquaculture each year (Statistics and Information Service of the Fisheries and Aquaculture Department, 2012) for use as human food. Yet damage to world ecosystems from common carp invasion exemplifies the problems of exotic species introduction, the efforts to reduce the negative effects of invasions, and the length of time that invasive aquatic species remain as nuisances.

Considerations over intentional introduction of exotic aquatic animals are studied in order to weigh the consequences of introduction versus benefits. Notably, tilapia, Chinese carp, and ornamental fish are important commercial fish with invasive reputations in aquatic ecosystems. Over the course of human history, more than 50 000 nonnative species, including many aquatic animals, have been introduced into North America. Some of these species, such as wheat, rice, cattle, and poultry were introduced as sources of food and now provide more than 98% of the US food system valued at approximately US$800 billion year^{-1} (Pimentel *et al.*, 2005).

Methods for Slowing or Reversing the Effects of Aquatic Invasions

Once an invasion starts, control of further invasion and reversal becomes difficult if not impossible to attain. Water is a difficult medium to operate a species location and for removal operation. Therefore, few aquatic invasive introductions have been reversed, unless in small confined water bodies where toxic substance or draining are used to eliminate the species (Clearwater *et al.*, 2008). More complex methods include release of sterile males; release of species-specific disease or predators; or removal by netting, angling, or electrofishing.

Responses to Aquatic Invasive Animals Have Included the Following Ideas

(1) Coordination of local, state, regional, federal and international activities, and programs pertaining to invasions; (2) control and manage the introduction and spread of invasive

 doi:10.1016/B978-0-444-52512-3.00203-5

species through education and outreach; (3) prevent the establishment of invasive species populations through early detection and rapid response programs; (4) control or eradication of established invasive species through cooperative management activities designed to minimize impacts to nontarget species; (5) monitor the distribution and impacts of invasive species to determine management priorities; (6) develop needed research on impacts and control of invasive species; and (7) prevent the introduction and spread of invasive species by national and international regulatory efforts.

Policies regulating invasive aquatic animals are complicated by international trade pressures. Decisions made to improve food availability or to improve economic status may cause damages that last for 500 years. Risk assessment models are needed in order to determine regulatory policy (Keller *et al.*, 2007).

Examples of Aquatic Invasive Animals of Global Importance

Salt Water

Asterias amurensis *(northern Pacific sea star)*

Originally from coastal waters from Russia to Japan, the sea star has moved into new locations, further south, where it preys on a wide variety of commercial and ecologically important species. This sea star is native to cool waters but has adapted to waters up to 20 °C and a wide range of salinity. Severe damage to bivalve fisheries is predicted due to invasion of the northern Pacific sea star (Ross *et al.*, 2002). A large part of the northern Pacific sea star diet is the blue mussel, *Mytilus edulis*, but in the absence of this preferred food, many other benthic animals are eaten (Barkhouse *et al.*, 2007). Eradication of the northern Pacific sea star in open water would be difficult and probably impossible; therefore, a system of prevention and exclusion has been adopted in order to prevent further introductions (Dommissee and Hough, 2004). Targets for regulation include ballast water, water intakes on ships, marine-based aquaculture gear and stock, fishing gear, recreational gear and vessels, mooring lines, and vessel hulls. Ballast water exchange, where 95% of the original water is replaced with deep ocean water, has been accepted as a possible means of northern Pacific sea star exclusion. Monitoring programs are in place with hope to identify the invader in new locations so that eradication efforts might be used.

Impact from invasive northern Pacific sea star amounts to billions of dollars of impact to commercial fisheries and potential extinction of marine species found in the invaded areas. Tasmania has already experienced fisheries reductions. Japan, near the native range of the northern Pacific sea star, must deal with this pest to their mollusk culture industry. Spread to the coast of North America by debris from tsunamis and typhoons is also anticipated. As monitoring programs are established by more countries (Bax *et al.*, 2006), there is hope that future expansion of the range of the northern Pacific sea star may be limited, possibly using genetic sex-ratio distortion.

Carcinus maenas *(green crab)*

Moved from Europe and north Africa primarily by ships since the 1800s, the green crab eats important mollusk species including Manila clam (*Venerupis philippinarum*) and displaces native crustaceans (Dungeness crab, *Cancer magister*). Note that the Manila clam is an introduced species in North America but has become an important addition to commercial shellfish harvesting. The dispersal of the green crab is mainly by ships, but other human activities are to blame, including intentional stocking (Klassen and Locke, 2007). Once introduced, the green crab can be moved by ocean currents into areas with suitable salinity (above 22 ppt) and temperature (10–22.5 °C) (Hitchcock *et al.*, 2004).

Dramatic reduction in soft clam (*Mya* sp.) and other mollusk harvests have followed invasion of the green crab. Mollusks are vulnerable to green crab at <15 mm sizes (Sanchez-Salazar *et al.*, 1987) and the reduction of spat limits mollusk populations. Green crab foraging changes the estuary bottom in such a way that erosion or saltwater grass damage may occur (Lafferty and Kurvis, 1996; Davis *et al.*, 1998). Minor uses for harvested green crabs are small compared to the value of lost shellfish harvest as approximately 40% of shellfish may be lost to green crab predation in a single year (Grosholz *et al.*, 2001). Trapping remains a possible suppression method for green crab, but evaluation of economic benefits of controls is lacking. Historic losses between US$719 million and US$805 million to the shellfish harvesters on the East Coast of the United States occurred over a 30-year period (Abt Associates, Inc, 2008).

Eriocheir sinensis *(Chinese mitten crab)*

Native to Asia, the Chinese mitten crab has been introduced to Europe and North America. A voracious eater, it eliminates invertebrate populations during mass migration. It contributes to shoreline erosion by burrowing. Managing crab populations by capture during environmental changes (salinity or temperature) may cause a population decline; however, ballast water remains a vector for reintroduction and spreading (Garcia-de-Lomas *et al.*, 2010). Chinese mitten crabs have spread to the West and East Coasts of North America where damage from the crabs is only recently reported (Dittel and Epifanio, 2009). Tolerant of freshwater, the Chinese mitten crab is a danger to freshwater stream and river ecology and has been observed in the Great Lakes of North America (Nepszy and Leach, 1973). Rice growing areas near the coastal streams are vulnerable to damage from Chinese mitten crab invasion as migration of 1000 km from salt water is possible.

Established populations of Chinese mitten crab, after causing damage, have been observed to decline due to a nearly complete reduction of adult crabs. Evidence of mated females does not necessarily indicate established populations (Benson and Fuller, 2014). Well established populations exist in Europe and Asia. Migrations downstream occur in the fall in Northern Hemisphere locations and young crabs travel back upstream the following year. Worth more than US$1.25 billion year^{-1} as food in China, few countries allow legal possession of Chinese mitten crab (Veilleux and de Lafontaine, 2007). Therefore, legal status changes must occur in order to use trapping as a control method.

Mnemiopsis leidyi *(American comb jelly or sea walnut)*

Introduced to eastern European seas from estuaries of North and South America by ballast water discharge, the American

comb jelly or sea walnut competes with commercially and ecologically important young aquatic animals for food. Destruction of the Baltic Sea ecosystem is an example of the danger of American comb jelly introduction. Decline, by half, in zooplanktivorous fish populations can open the ecosystem to invasion by the American comb jelly (Purcell *et al.*, 2001). Widely distributed, the American comb jelly is deemed improbable to eradicate but many studies of biological controls have been undertaken with the eventual determination that nontarget damage will occur. One genus, *Beroe*, feeds on gelatinous zooplankton and may serve as a control (Galil, 2008). In the Black Sea, *Beroe ovata* increased as American comb jelly population declined – a possible cause and effect that could lead to biological control measures (Shiganova and Malej, 2009). *Beroe* sp. and *M. leidyi* are sometimes moved simultaneously in ballast water.

Potamocorbula amurensis *(Amur River clam)*

Recently introduced to cool waters off California in North America, large populations of Amur River clam develop without predator pressure. The Amur River clam has established as 95% of the biomass in some locations and is the dominant benthic species in San Francisco Bay. This efficient filter-feeding mollusk has caused significant reduction in plankton in the infested estuary (Greene *et al.*, 2011). Birds can almost eliminate the clam in shallow water, but deepwater populations reestablish the shallow water population in later seasons. Crabs and fish will eat the clam when their mouths are large enough, notably Dungeness crabs and white sturgeon. The Amur River clam may be suppressed by cool water temperatures in its native range, but can thrive in warmer water and over a wide salinity range. However, early life stages suffer from very low salinity. Pelagic life stages are moved in water currents, but spread has occurred due to the influence of shipping (Thompson and Parchaso, 2012). Densities as high as 10 000 per m^2 can exist and harvesting of high density populations provides animal and aquaculture food in some countries (Carlton *et al.*, 1990).

Fresh Water

Clarias batrachus *(Asian walking catfish)*

Established in southeast Asia to Australia and accepted as an aquaculture species, the Asian walking catfish was introduced to the United States in the 1900s. Rapid spread occurred in Florida south of the frost line from 1968 to present. A carnivorous catfish, it displaces native fish and preys on native aquatic animals (Barber and Babbitt, 2003). The Asian walking catfish has been spread primarily as an aquaculture species, in the aquarium trade, or stocked intentionally in natural waters. It has been declared established and invasive in Florida, USA, but is established elsewhere and not considered invasive (Courtenay *et al.*, 1974; Welcomme, 1988). The Asian walking catfish rapidly spread to 24% of freshwater in Florida where it began to displace native sunfish and catfish species.

The Asian walking catfish is a tropical species with euyhaline ability surviving to 10 °C and 18 ppt salinity. Prevention of introduction is the best control. Carnivorous and aggressive feeding behavior places the Asian walking catfish without competition in most ecosystems. Relatively easy reproductive needs allow spawning in cavities in static waters near 25 °C. The characteristics that make the Asian walking catfish a suitable aquaculture species also enhance its invasive qualities. Where commercial fishing has waned, the Asian walking catfish has little pressure to control population expansion as long as fish, amphibian, or invertebrate food sources are available. Regulation of Asian walking catfish intends to limit distribution and along with education efforts may help restrict the catfish to existing locations (Brogan, 2003).

Ctenopharyngodon idella *(Grass carp)*

Spread by government agencies and private individuals for aquatic plant control by biological means, the green carp (**Figure 1**) has escaped and become established in river systems that have a high habitat suitability rating (depth, current, temperature, and length). A native of the Amur River area of Russia and China, the grass carp has been released or escaped into most temperate and tropical areas of the world. Grass carp impact on the environment is largely an alteration of the environment that leads to decline of vascular aquatic plants and an increasing in phytoplankton with corresponding effects on native fish species (Bain, 1993). Grass carp are recommended as a biological control for succulent aquatic plants and triploid populations have been produced in order to limit reproduction after escapement (US Army Corps of Engineers, 2012). High value for grass carp has allowed successful development of functionally sterile fish for stocking as aquatic plant control agents. Population expansion has continued as some governing entities allow stocking of diploid grass carp. Therefore, electric gates and exclusion devices have been installed on rivers in efforts to restrict fish migration away from existing locations.

Cyprinus carpio *(common carp)*

Popular in Europe and across Asia, the common carp has spread as an aquaculture species but escapes into natural waters of temperate and tropical climates. Rapid reproduction and survival in a broad range of habitats allows the continued spread of common carp. A few isolated watersheds remain free of this species. Eventually most temperate and high mountain tropical ecosystems will be invaded by common carp

Figure 1 Grass carp. Courtesy of USDA APHIS PPQ Archive, USDA APHIS PPQ, Bugwood.org.

(Zambrano *et al.*, 2006). Common carp are part of the carp-polyculture system, so have been cultured for more than 6000 years. Ornamental koi are common carp strains with popularity for aquarium and water garden enthusiasts. Widespread in the eighteenth century before concerns for invasive introductions, common carp have been established in populated areas of most continents. Commercial fisheries are developed in Europe, North America, and Asia for common carp. Carp pituitary glands are a secondary product collected and used to induce spawning of cultured fish. Still, prolific spawning has insured that common carp populations will continue to spread throughout suitable habitats. Saunders *et al.* (2010) discussed Koi herpesvirus as a possible control for *Cyprinus carpio*. However, nontarget impact may affect valuable cultured koi, ghost, and common carp stocks. Also, common carp that were not killed would recover to be lifetime carriers of the virus. Predatory fish including pike and bass suggested as controls for confined populations of common carp. Predatory fish are a nonselective control that may have a place in common carp management, so management objectives that insure healthy native predator fish populations may limit exotic invasive fish impact. However, dense populations of common carp may not be controlled or may reach sizes that exceed predator gape width so that control is not possible (Drenner *et al.*, 1997). Largemouth bass are considered invasive species when outside their native range.

Dreissena polymorpha *(zebra mussel)*

Introduced by ballast water discharge into fresh waters around the world, the zebra mussel (**Figure 2**) causes displacement of native mollusk species, competition for food, and biofouling damage (Benson *et al.*, 2012). Canal systems in Europe allowed zebra mussels to spread to almost all drainages during the eighteenth and nineteenth centuries. Able to populate at 700 000 per m^2 zebra mussel fouling affects power generation, maritime industries, and water supplies. Potential exists for zebra mussels to spread to all freshwater navigation waters in temperate regions of the world. Phytoplankton filtered and consumed by zebra mussels competes with zooplankton and other aquatic animal larvae (Frischer *et al.*, 2005). Water clarity increases over zebra mussel reefs (Ackerman *et al.*, 2001; Holland, 1993). Lakes change from phytoplankton-dominated to macrophyte-dominated communities after zebra mussel invasions.

Figure 2 Zebra mussel. Courtesy of Amy Benson, US Geological Survey, Bugwood.org.

Monitoring and control of zebra mussel cost an average of US$30 million per year in the Great Lakes area of the United States during the mid-1990s. One thousand four hundred and ninety water-using companies used monitoring, chemical treatment, retrofitting, or mechanical removal and in some cases did not use surface water due to zebra mussel presence (Park and Hushak, 1999). Prevention is proposed as the best method to contain zebra mussels in current locations. However, monitoring and enforcement regulations are needed and must be applied diligently. Eradication works in closed systems but is always costly. Open system treatments would cost tens of millions of dollars, even if the technology were available (Western Regional Panel on Aquatic Nuisance Species, 2010).

Lithobates catesbeianus *(American bullfrog)*

Intentional introductions and escape from aquaculture have moved the bullfrog from North America to many countries across the world. As carriers of the chytrid fungus, they could contribute to the decline of native amphibians. Bullfrogs, outside their native range, compete with and eat endangered amphibians and fish. Direct removal and habitat elimination may be useful methods to reverse bullfrog invasions (Adams and Pearl, 2007). Trapping and electro shock efforts may be effective for controlling invasions in localized habitats (Orchard, 2011). These methods require a substantial investment of labor in order to achieve control of bullfrogs.

The chytrid fungus, *Batrachochytrium dendrobatidis*, is present in at least two strains. The bullfrog is susceptible to one but may carry the other. However, over time infection load decreases in bullfrog skin so that the bullfrog may not be an efficient carrier of this fungal disease of amphibians (Gervasi *et al.*, 2013). It has been proposed that the global trade in amphibians has led to development of a hypo virual strain of the chytrid fungus. This hybrid of strain is made possible by sexual reproduction of the chytrid fungus (Schloegel *et al.*, 2012) and may be one of the reasons the fungus is devastating in one location but not in another. Also, decline in fungus presence on bullfrog skin may explain some of the variation in chytrid fungus expression during bullfrog invasions.

Micropterus salmoides *(largemouth black bass)*

Introduced in many parts of the world as a sport fish, largemouth bass are predatory fish adaptable to temperate and tropical lakes and streams. The largemouth bass eats and sometimes eliminates native fish and crustaceans (Gratwicke and Marshall, 2001). Largemouth black bass, stocked in ponds or lakes as sport fish, will travel upstream and downstream into habitats of native carnivorous fish. Competition for food

sources including forage fish and crustaceans can have damaging effects on native bass, trout, and pike. As a result more homogeneous fish communities alter plankton and habitat to the exclusion of diverse native aquatic ecosystems (Jackson, 2002). Sport fish, including lake trout, brook trout, and walleye are affected when *Micropterus* are established. Although government agencies have been responsible for introductions in the past, unauthorized introduction of largemouth black bass are more likely to cause damage to sensitive ecosystems. Therefore, educational and regulatory policies should be developed and enforced as a means to limit expansion of largemouth black bass range.

Oncorhynchus mykiss *(rainbow trout)*

Rainbow trout was introduced from western North America across the rest of North America and much of the cool water habitats in the world. A popular sport fish that can displace native trout and consumes ecologically important fish and invertebrates. An example is the displacement of cutthroat trout (Seiler and Keeley, 2007). Escapement from aquaculture facilities may carry disease to native fish, lower vigor by hybridization with resident trout populations, or compete for limited forage in oligothrophic water bodies (Patterson and Blanchfield, 2013). Rainbow trout disperse rapidly after escape and may travel 350 km in a short period of time.

Increased aquaculture of rainbow trout in Europe and mariculture in Chile and Norway intensify the danger of escape and impact on native fish. Study of rainbow trout infected with sea louse observed movement between farms near the source of escapement and a reduction of sea louse abundance over several months (Skilbrei, 2012). Rainbow trout remained in the farm area but did not rely on eating wasted feed from the farm, rather subsisted on local forage and contributing to the impact of the farm on local fauna. Recapture of escaped rainbow trout has been suggested as a means to reduce invasive impact (Skilbrei and Wennevik, 2006). Gillnets are one means of recapture that appears to catch more escaped fish than wild fish.

Oreochromis mossambicus *(Mozambique tilapia)*

Mozambique tilapia and its hybrids are popular aquaculture fish noted for tolerance to harsh environments in warm and tropical waters. Tilapias spawn prolifically and are voracious omnivores. The Mozambique tilapia was stocked in aquaculture ponds and natural waters during the last half of the twentieth century, escaping into tropical and subtropical fresh and estuarine ecosystems (Courtenay and Robins, 1989). In the Philippines, Mozambique tilapia are established in brackish water farms, rivers, and swamps. An endemic fish, the snarapan, has been reported extinct at least partly due to invasive Mosambique tilapia (Canonico *et al.*, 2005). Research observations, while significant, are generally incomplete for comparing conditions before and after Mosambique tilapia introductions. Policy needed to manage established populations and to protect native fisheries require more research in order to settle ambiguous observations and to show the cost versus benefit of introductions. The argument that tilapia feed in their own niche with little damage to other fish seems to ignore the effect of introduced tilapia on native tilapia and cichlids that share food sources. Introduction of Mozambique tilapia after careful consideration of competitors, food availability, and temperature barriers may be accomplished with proper government oversight; however, uncontrolled introductions are most dangerous to ecosystems.

Oreochromis niloticus *(Nile tilapia)*

The Nile tilapia (**Figure 3**) has been intentionally spread across the world as an aquaculture food fish. Sometimes confused with the Blue tilapia (*Oreochromis aurea*), the Nile tilapia has escaped aquaculture facilities to warm water river systems and lakes. Nile tilapia eat small benthic organisms and detritus, so may not compete directly with native fish that eat other food items such as larger invertebrates and fish (Peterson *et al.*, 2006). Competition for space forces native forage fish into closer contact with predators (Martin *et al.*, 2010). Nile tilapia may invade most tropical waters and establish reproducing populations (Zambrano *et al.*, 2006). Estuarine waters are potential habitats and pathways for travel to other watersheds during Nile tilapia escape (Lowe *et al.*, 2012). Diluted salinity during wet years increases migration potential between coastal habitats. Nile tilapia have established feral populations in most, if not all, countries where it has been introduced (Vicente and Fonseca-Alves, 2013). Temperature limits must be well outside the tolerance range of Nile tilapia in order to limit establishment.

Impact of Nile tilapia on native ecosystems is controversial due to the ability of Nile tilapia to feed at a different trophic level than many native fish. Fish biomass may increase after Nile tilapia establishment without significant effect on diversity of native fish assemblies, even after 7 years (Arthur *et al.*, 2010). Long-term effects are difficult to predict and objective impact observations are limited. In Nicaragua, 80% of native cichlids were lost after Nile tilapia introduction and in Madagascar, decline in native fish diversity was correlated to tilapia introduction. Examination of the stomach contents of nonnative Nile tilapia in Mississippi, USA revealed food organisms outside its traditional detritivorous niche (Canonico *et al.*, 2005). Attempts to eradicate introduced Nile tilapia have failed except in isolated ponds and pools.

Figure 3 Nile tilapia. Courtesy of US Geological Survey Archive, US Geological Survey, Bugwood.org.

Pomacea canaliculata *(channeled apple snail)*

Native to South America, the apple snail was transferred by the food and aquarium traders to North America and Asia. Damage to crops (rice and taro) and sensitive wetland vegetation has been extensive. Apple snails can carry diseases transmissible to humans such as the rat lungworm (*Angiostrongylus cantonensis*). Introduced to Taiwan in the 1980s, apple snails have spread through southeast Asia and southern China and now into Australia. The channeled apple snail was introduced as a human food into the Hawaiian islands in 1989 (Cowie, 1998). North America has also experienced uncontrolled apple snail establishment largely because suitable predators are not present in numbers adequate to control this snail (Howells, 2003).

Rhinella marina *(cane toad)*

Native to Central and South America, the cane toad (**Figure 4**) was utilized as a biological control for agricultural insect pests in the early 1900s. When introduced, it spreads over wide ranges, as in Australia where it moved more than 2000 km over 75 years. Cane toads are poisonous and predator populations decline in cane toad-infested areas while prey populations increase (Shine, 2010). Some Australian predators recovered 10 years or more after cane toad invasion by learning to avoid the toads. So, no evidence of species extinction has been reported from cane toad infestation in Australia. Barriers to expansion of cane toad infestations include restricting access to water by fencing or draining (Tingley *et al.*, 2013). Using the cane toad poison to lure tadpoles to traps may improve removal efforts (Crossland *et al.*, 2012). Lungworms (Nematoda) may be useful parasites for cane toad control due to differential susceptibility between cane toad and native amphibians (Phillips *et al.*, 2010). Other promising controls include the use of hormones to lure cane toad tadpoles to eggs so that cannibalization will reduce that invading population (Crossland *et al.*, 2011).

Salmo trutta *(brown trout)*

Transported from Europe in the late 1800s, the brown trout is used for aquaculture and fisheries stocking. The brown trout may displace native and endangered fish by competition and predation. Genetic dilution of native salmonids occurs when brown trout cross with salmon (Krueger and May, 1991). Brook trout and golden trout are vulnerable to brown trout competition (Pister, 1991). Prey species, similar to the Modoc sucker, have gone into decline due to brown trout predation.

Containment efforts are regulatory and educational in nature. An integrated approach to improve the status of competitive species, like brook trout, has begun in New York, NY, USA. Habitat improvements and water quality improvements, favoring brook trout, are expected to limit brown trout (Neumann and Wildman, 2002). Piscicides have been applied to kill brown trout in areas of golden trout habitat, then fish barriers were installed to isolate golden trout and exclude brown trout (Pister, 1991). In Australia, regulations governing introductions and fish movement are intended to keep brown trout from spreading beyond existing locations. Repeated electrofishing can selectively reduce brown trout, provided labor and equipment resources can be made available (Caudron and Champigneulle, 2011).

Glossary

Biotic resistance hypothesis The hypothesis that competition and other biotic interactions with native plant species explain the tendency for less disturbed plant communities to suffer relatively low rates of invasion.

EICA hypothesis The hypothesis that the lack of native pathogens, predators, and herbivores experienced by nonindigenous plant species in new habitats allows re-allocation of resources away from defense and toward development and growth, in turn resulting in increased invasiveness.

Exposure studies Studies that are conducted to determine the level of risk posed by an organism to the environment, often involving tiered assessment of the likelihood of each step of a given hazard scenario occurring.

Invasion barriers Biotic, abiotic, and geographical factors that prevent nonindigenous plant species from moving between invasion stages.

Naturalization The process during which a plant species establishes viable populations in a new location.

Nontarget environments Environments that may be placed at risk by the unwanted effects of a novel organism that lies outside the area originally targeted for its release.

Phenotypic plasticity The ability of an organism to alter its phenotype in response to changing environmental conditions.

Polyploid An organism containing more than two sets of homologous chromosomes.

Preadaptation In the context of invasive species, referring to the ability of nonindigenous species to survive in newly colonized habitats by expressing preexisting adaptive traits.

Propagule pressure A measure of the number of individuals of a nonindigenous species released into a given region, incorporating both the number of release events and the number of individuals per event.

Introduction

As human societies have developed they have increasingly broken down the spatial barriers that historically separated species, communities, and ecosystems. The result has been an ever-increasing rate of long-distance dispersal of both animal and plant species to new habitats and the concomitant taxonomic homogenization of previously distinct floral and faunal assemblages. Today, this process continues virtually unabated, and invasive species are considered to pose one of the primary contemporary threats to biodiversity conservation and agricultural productivity in both native and agricultural systems on a global scale. Indeed, it is no exaggeration to state that synergistic interactions between invasive plants and other agents of global change, including anthropogenic global warming (AGW), rising atmospheric carbon dioxide concentrations, nitrogen deposition, habitat fragmentation, and disturbance, are likely to leave few if any natural or agroecosystems unchanged over the next century.

The economic costs of plant invasions alone are staggering. It has been estimated that in 2005 the direct annual economic impact of weedy plants on US agricultural production exceeded US$ 25 billion, with losses mainly caused by reduced crop and pasture yields and the cost of weed control (Pimentel *et al.*, 2005). Similarly, a thorough assessment of the economic impact of weeds in Australia in 2004 revealed annual losses associated with agriculture of AU$ 4 billion, and costs of invasive species management in natural systems of at least AU$ 19 million. A further AU$ 80–90 million was spent on weed management and research by public authorities and the Australian government (Sinden *et al.*, 2004). The direct impacts of nonindigenous species on natural and seminatural ecosystems are also severe: In addition to direct negative impacts on biodiversity such as species extinction, many of the most aggressive nonindigenous species alter the structure, composition, and function of recipient plant communities, processes that are driving change in ecosystems on a global scale.

For these and other reasons, plant invasions have long been of interest to ecologists. In the five decades since Charles Elton published his classic 1958 book 'The Ecology of Invasions by Animals and Plants' (Elton, 1958), ecologists and agronomists have sought to develop a unified understanding of how, why, and under what circumstances plant invasions occur, and the strategies that may be most successfully adopted for their control. Although much of this research has proved extremely fruitful, leading to successful systems for both identifying potentially invasive species and managing their impacts once established, some areas remain difficult or controversial or are compromised by a lack of data. Indeed, at the most basic level our understanding of the biological mechanisms that allow some species to dominate plant assemblages following introduction to new habitat remains limited, and integrating new data and theory from across ecology, evolutionary biology, and ecophysiology will be a critical ongoing challenge for invasion biologists in coming years (Richardson and Pyšek, 2008).

This article is intended to provide a basic overview of current knowledge in invasion biology and to highlight active areas of research. The authors first describe the basic invasion

 doi:10.1016/B978-0-444-52512-3.00202-3

pathway, and consider the barriers that nonindigenous species must overcome before becoming invasive in a new geographic range. They illustrate key principles associated with the invasion pathway using data from Australia, which provide an excellent case study of invasion of a geographically isolated land mass by introduced plants. Then they consider evolution and other genetic processes associated with the establishment and spread of invasive species and turn our attention to the mechanisms of their impact on natural ecosystems and their roles as ecosystem engineers. They then discuss two current questions of great importance in contemporary invasion biology. The first is whether climate change is likely to confer an overall fitness advantage on nonindigenous species relative to cooccurring native plant species, and why. The second is whether genetically modified crops or their adoption is likely to cause increased weed pressure on target and nontarget natural and agricultural ecosystems – a matter of great controversy over the past decade. They conclude by briefly discussing opportunities for future research.

Unfortunately, invasion biology has long been plagued by the use of vague or contradictory terminology to describe processes or stages of the invasion pathway and the plants involved (Richardson *et al.*, 2000). The authors begin, therefore, by defining some important terms that will be used throughout the article. The term nonindigenous plant species (NIPS) refers to species occurring outside of their native range, and is used interchangeably with terms such as 'alien' and 'exotic' species. Invasion refers to the process in which introduced plants reproduce outside of the original immediate area of introduction and does not include reference to any damage cause by the plant. Weeds are invasive species, especially in agricultural systems, that cause harm or are otherwise undesirable.

The Biology of Plant Invasions

The Invasion Pathway and the Australian Experience

The end result of the successful introduction of NIPS to new regions can be a situation where introduced species become geographically widespread, overabundant, and cause an enormous amount of ecological and economic damage. To get to this situation, however, plant species require the ability to traverse several invasion stages (Theoharides and Dukes, 2007) and to surpass several important 'invasion barriers' (see **Figure 1**; Satai *et al.*, 2001).

The first stage of the invasion pathway, 'Transport,' is associated with NIPS overcoming a significant natural barrier of geography, one that NIPS could not disperse across naturally. Somehow, NIPS must cross vast distances over land and/or sea. The most striking characteristic of modern-day plant invasions is that this transport stage is facilitated by a diverse range of human activities. For instance, many plant species are deliberately brought into new regions for ornamental purposes (Groves *et al.*, 2005). A good example of global translocation of NIPS is the Singapore Daisy (*Sphagneticola trilobata*), which was originally brought into Australia as a garden ornamental and deliberately planted as a roadside and railway embankment stabilizer in the north-east of the

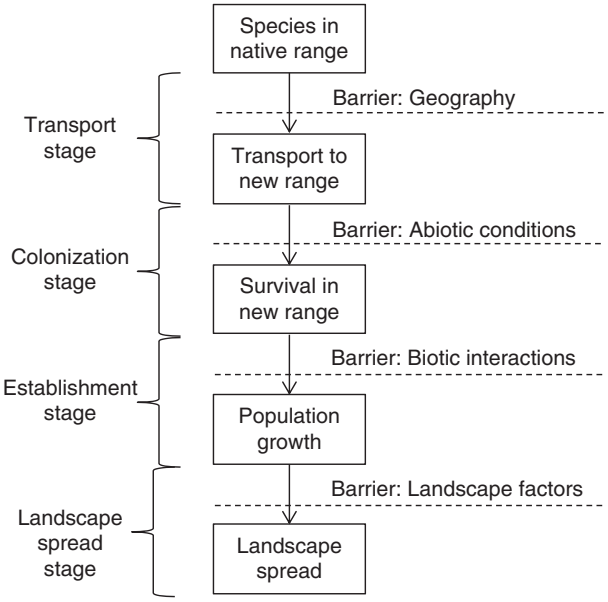

Figure 1 Typical invasion pathway showing the four main invasion stages (transport, colonization, establishment, landscape spread) and barriers faced by plants associated with each stage. Adapted from Hellmann, J.J., Byres, J.E., Bierwagen, B.G., Dukes, J.S., 2008. Five potential consequences of climate change for invasive species. Conservation Biology 22, 534–543.

continent. Some NIPS have been introduced to new regions to be used for a variety of purposes. For example, Mesquite species (*Prosopis* spp.) were introduced to Australia as fodder for livestock and as ornamental species in station homestead or town gardens, and were also used in mine dumps and other soil stabilization programs. Importantly, a large number of NIPS can be introduced to new regions outside their natural geographic ranges accidentally, and thus can be considered unintentional introductions. For instance, Whiskey Grass (*Andropogon virginicus*) was introduced accidentally to Australia when it was used as protective packaging for American bottles of whiskey.

It would appear that irrespective of the reason for introduction, there is the potential for any NIPS to become a serious agricultural weed, whether introduced purposefully or accidentally. Indeed, all three plant examples provided above are now considered serious weeds of Australian agriculture.

The second stage of the invasion pathway, 'Colonization,' or 'Introduction,' can be successfully traversed by NIPS in one of two ways. First, some species need to overcome a barrier in the form of cultivation. For example, many NIPS exist in cultivation beyond the limits of their native ranges, but they do not form self-sustaining populations outside of cultivation. The key concern here is the fact that some species can escape cultivation to become established in the wild. Using Australian examples to illustrate this idea, two extreme examples of escapees from cultivation, which are considered to have 'jumped the garden fence,' are Paterson's curse (*Echium plantagineum*), which costs agriculture AU$30 million per year, and Lippia (*Phyla canescens*), which costs the grazing industry an estimated AU$38 million per year. The second way NIPS can traverse the colonization stage is by avoiding the cultivation

barrier; this happens when a species has been introduced accidentally by humans directly into the new environment.

More than 27 000 NIPS are known to have been introduced to Australia; however, only approximately 10% of these species have surpassed the third stage of the invasion pathway, the 'Establishment' stage. For plants, this is also commonly referred to as the 'Naturalization' stage. An invasion ecology generality that appears to be fairly consistent globally is the Tens rule (Williaimson and Fitter, 1996), whereby only approximately 10% of the introduced flora of a region will ever become naturalized (although it is worth noting that this is an average figure and recent studies have documented much higher percentages in some regions of the world). Furthermore, approximately 10% of naturalized NIPS will transition to become invasive weeds (see below, the 'Landscape spread' stage). Interestingly, NIPS introduced as garden ornamentals are the dominant source of new naturalized plants and weeds in Australia. Of the roughly 2700 NIPS now known to be established in the Australian environment, approximately 1800 species are escaped garden plant species. The rate of increase in the number of naturalized plant species in Australia has tended to be linear until recent times. Recent work has reported an increase in the number of species naturalizing in Australia, leading to the conclusion that the rate of naturalization is increasing.

What does it take for NIPS to become naturalized? A species is generally considered naturalized when there is evidence for the existence of a self-sustaining population over a period of time corresponding to multiple generations. It is rare to find published work that compares the attributes of species that have become naturalized with other species introduced to the same region that have not become naturalized. Recent comparative work, however, for North American plant species that have become naturalized in Europe has shown that introduction history, in particular increased planting frequency, is an important determinant of current naturalization success among these exotic invaders in Europe (Bucharova and van Kleunen, 2009). Life-history traits of species can also be important, but this depends on plant growth form. For example, the naturalization success of trees was found to increase positively with maximum plant height and seed spread rate. This was not the case for other life forms.

The fourth and final stage of the invasion pathway is 'Landscape spread.' Arguably, this is the most important part of the invasion pathway. If NIPS fail to get past the barriers of dispersal and subsequent survival during population spread in the introduced range, then they do not have the potential to become serious weeds of the environment and/or agriculture. Few species pass through this invasion stage successfully. Indeed, current estimates of the number of invasive NIPS in Australia put the number at approximately 130 species. This figure is currently being reviewed, and it is likely to nearly double in the future to nearly 250 species. Interestingly, this puts the number of invasive NIPS in Australia at 10% of the total number of naturalized species, a percentage that follows the aforementioned Tens rule.

A fundamental question of invasion ecology is just how long it takes NIPS to shift from the state of naturalization to become invasive. The length of time between these two states is referred to as the lag time or lag phase (although it can sometimes refer to the period of time between introduction and invasion). Lag times are notoriously difficult to determine, as it is not often known when a species has become naturalized. Nevertheless, some studies have described lag times and it is clear that these can vary considerably. The majority of species do go through a lag phase, which appears to be approximately 50 years as a minimum for NIPS in Australia. Recent work examining 23 NIPS introduced to Hawai'i that eventually became invasive pests has revealed that the average lag time between introduction and first evidence of spread is 14 years for woody plants and 5 years for herbaceous plants. Such short lag times provide equally worrying short times for managers attempting to manage the spread of new invaders.

Perhaps one of the most important questions for invasion ecology and for the quest for an understanding of just what it is that makes species invasive is what traits invasive NIPS possess that allow them to become successful invaders (Drenovsky *et al.*, 2012). One approach that has been adopted over the years has been to compare the traits of invasive NIPS with resident native species. Unfortunately, this approach has yet to reveal any globally consistent biological differences. A more relevant approach has been the exploration of traits that differ between naturalized noninvasive NIPS and invasive NIPS. The idea here is that by using a 'target-area' approach, one can compare NIPS that cooccur within their introduced range for fundamental differences in their attributes. Given its long-term geographic isolation, but relatively recent settlement by nonindigenous peoples, Australia provides a unique opportunity to study the invasion process and the factors that contribute to invasion success in NIPS (Murray and Phillips, 2010; Phillips and Murray, 2012). A substantial body of evidence is emerging to show that invasive NIPS differ from noninvasive NIPS in both their introduction history and life history. Introduction history refers to traits of species related to where they have been introduced from, why they were introduced, and how long they have been resident in the novel range. Indeed, residence time has emerged as a highly important trait for successful invasion. NIPS that have been present in the new range for longer periods of time are more likely to have become invasive. Life-history traits of species refer to those characteristics of species related to growth, survival, and reproduction. Interestingly, recent work for Australia has shown that species with small seeds (correlated with increased reproductive output) are more likely to become invasive than larger-seeded species. Furthermore, the seeds of invasive NIPS are more likely to have had more resources invested by the parent plant into their dispersal adaptations (e.g., wings for wind dispersal, fleshy fruit for dispersal by vertebrate foragers).

Evolution in Invasive Species

One of the most interesting paradoxes of invasion biology is that many invasive species, despite originating from numerically small founder populations, adapt extremely well to new environments and undergo rapid population growth and range expansion. Because bottlenecked populations typically have low genetic diversity and hence should have reduced evolutionary potential, it is argued that this phenomenon could be simply explained by high levels of 'preadaptation'

among the most successful exotic species with traits that lead to high fitness in new environments (e.g., high dispersal rates and competitive ability). Such species may remain highly invasive despite suffering some diminishment of genetic diversity in response to inbreeding.

Although this may be broadly true, the fact remains that many of the best examples of rapid evolution come from invasive NIPS, and the critical role that evolutionary adaptation can play in the invasion process is now becoming widely recognized among biologists (Whitney and Gabler, 2008). Indeed, mounting evidence suggests that a range of genetic processes, even among small founder populations, can facilitate plant invasion of new habitats (Lee, 2002). Most of these involve increases in additive genetic variance, which must be present for evolution to occur in response to selection pressure. Two of the most important mechanisms include hybridization of invasive species with close relatives in the new range (interspecific) and admixture of previously separated genotypes in the introduced range (intraspecific). One of the most widely cited examples of interspecific hybridization leading to increased hybrid invasiveness is that of *Spartina anglica* in the British Isles (Raybould *et al.*, 2008), an allopolyploid derived from *Spartina maritima* and *Spartina alterniflora*. *Spartina anglica* is now a noxious weed, whereas the parental species have relatively limited distributions. 'Polyploid' hybrids usually have greater fitness than diploid hybrids, and allopolyploidy has been linked to invasiveness in a number of taxa.

Intraspecific genetic admixture is most likely in species with a history of multiple introductions, and can result in genetically diverse populations of invasive NIPS that have an increased evolutionary capacity (Frankham, 2005). Several other genetic processes can also apparently increase the fitness of invasive species. Additive genetic variance can be increased by conversion of epistatic or dominance variance by genetic drift following population bottlenecks; epistasis itself (interaction between different gene) provides a source of variance that could respond to selection pressure. In some species a small number of genes instead of total additive variance may play a critical role in determining plant fitness under new selection regimes. Of course, not all introduced species benefit significantly from these genetic processes; for instance, some invasive NIPS are known to have limited genetic diversity and evolutionary capacity as a result of small founder population size. All are also influenced to a greater or lesser extent by a range of factors such as genetic drift, small population size, trade-offs among fitness-related traits, and swamping of adapted genotypes by migration (i.e., migration-selection balance) that limit population adaptation and expansion in range-edge or marginal habitats.

Evolutionary theory suggests that adaptation should occur following selection for fitness-related traits that have a heritable source of genetic variation. Sources of selection in new habitats are myriad, including climatic factors, competition with resident species, or new grazing or predation regimes. There is compelling evidence (Colautti *et al.*, 2010) that many invasive species have undergone population differentiation or evolution in response to broad-scale climatic gradients within a matter of decades (e.g., *Echium plantagineum*, *Hypericum perforatum*, *Solidago altissima*, *Senecio inaequidens*, and *Lythrum salicaria*; Konarzewski *et al.*, 2012; Monty and Mahy, 2009), although the establishment of such clines is not ubiquitous. Mimicry is a fascinating evolutionary adaptation exhibited by some crop weeds in response to the strong directional selection typical of agricultural cultivation (Barrett, 1983). Under these predictable and repetitive selection regimes mimicry can develop in seed, which increasingly resembles that of the associated crop species in terms of weight, size, and overall appearance, or vegetative growth traits, which also can converge. Studies have shown that *Echinochloa crus-galli* var. *oryzicola*, for instance, is closer to rice in phenology, growth, and morphology than to its close relative *Echinochloa crus-galli* var. *crus-galli*. Rapid evolutionary responses to agricultural herbicide application also occur frequently, with crop weeds developing herbicide resistance. The implications of this process associated with the cultivation of genetically modified crops are discussed in another section of this article.

Over the past decade there has been much focus on the potential for plants to experience release from specialist natural enemies (herbivores and diseases) when moved outside of their native range, resulting in increased fitness (the enemy release hypothesis; Keane and Crawley, 2002). Theory suggests that plants experiencing reduced rates of herbivory will reallocate resources away from resistance or tolerance strategies to increased growth, provided that the production of defense chemicals or tolerance mechanisms comes at a fitness cost. Evidence for evolution of increased competitive ability involving this mechanism (known as the 'EICA hypothesis'; Blossey and Nötzold, 1995), along with other evolutionary processes, has been postulated as explaining the tendency for some NIPS to exhibit a lag phase before becoming invasive. Evidence for the EICA hypothesis was first observed in *Lythrum salicaria* but since then has only found partial experimental support; recently it has been suggested that resource allocation under enemy release may affect many fitness-enhancing traits, not just those relating to growth and competition.

Traditionally, much of the focus of research of invasion biology has been on developing an understanding of the demographic and life-history predictors of invasiveness, on their impacts on native and agricultural ecosystems, and on means for more efficient weed control in different settings. However, given the strong emerging links between genetic background, evolutionary capacity, and invasion dynamics, it is clear that treating invasive species as uniform entities with fixed genotypes will fail to adequately capture their likely behavior when faced with changing environmental conditions and selection regimes. One area where this clearly applies, for example, is in the modeling of weed spread under future climate change scenarios. Successful integration of evolutionary and ecological concepts into a more detailed and predictive understanding of the process of plant invasions will remain one of the most interesting but challenging aspects of invasion research for years to come.

Impacts of Invasive Species on Natural and Agricultural Systems

Invasive NIPS can have an impact on individual species to entire landscape scales through a wide range of genetic,

demographic, and evolutionary mechanisms (Levine *et al.*, 2003). These impacts can be direct, such as competition for light, water, and nutrients with native community associates, or indirect, involving complex changes to ecosystem processes. As with other components of the invasion process (Ehrenfeld, 2010), however, invasive NIPS differ significantly in their capacity to directly and indirectly drive change in recipient ecosystems. Determining when and how impacts arise, which species are likely to significantly transform ecosystems, and which communities are most susceptible to change has direct application to more effective management of extant invasive species and efficient restoration of degraded ecosystems once they have been removed.

Arguably the most obvious and socioeconomically damaging direct impacts of invasive NIPS occur in agricultural systems where competition for light, water, and nutrients by weedy species reduces crop yields to a point where intensive and costly control is required. These systems, which are characterized by both impoverished faunal and floral assemblages and abundant supply of resources, are especially prone to invasion, and many crop weeds are ruderal, r-selected (fast growing) species that are generally intolerant of competition and abiotic stress. It is estimated that globally weeds reduce crop yields by approximately 9%, although figures vary across crops and depend strongly on the crop protection measures used to reduce potential losses: less developed regions suffer considerably higher losses. Along with other crop pests, weeds are expected to pose a significant challenge to global food security in coming decades, and thus a range of strategies including the development of genetically modified herbicide- and pest-resistant crops (see Section Transgenic Plants as Invasive Species) are being adopted to enable more efficient weed control.

A great many ecological studies have quantified changes in the composition and diversity of terrestrial plant assemblages following invasion by NIPS, usually by comparing invaded with uninvaded communities. In many cases, competition is cited as the reason for loss of native species. This a plausible explanation because virtually all plants compete for a limited set of common resources (e.g., light, water, nutrients), but relatively few studies have investigated the implied competitive relationships among native and exotic species using formal removal or addition experiments, and the link between specific resources and competitive exclusion is often unclear. However, water and light competition associated with invasive species is a frequent driver of vegetation decline or change. *Carpobrotus edulis*, for example, is an invasive succulent plant that, by competing for water, affects the morphology and growth of cooccurring native shrubs in coastal California, while competition with annual exotic species for light during spring has been proposed as a key mechanism that has led to the decline of the native bunchgrass *Nassella pulchra* in Californian grasslands. Interestingly, the competitive advantage experienced by invasive species is highly dependent on resource availability; many invasive species are fast-growing species with high biomass production when resource supply is adequate but perform less well than native species in low-resource environments. Biomass production, in fact, is perhaps the most widespread process by which invasive species both directly and indirectly impact on native associates.

Invasive NIPS that are taller or denser than native associates or have novel traits can alter ecosystem attributes such as light regimes, soil moisture patterns, litter composition, and sediment deposition to such an extent that they become ecosystem engineers (also called transformers or keystone species). NIPS capable of fixing atmospheric nitrogen (nitrogen fixation) are one widely studied group that transform ecosystems by increasing soil nitrogen availability, which can significantly alter plant community structure and composition, especially in environments where soil nitrogen is low and there are few or no native nitrogen fixers. An excellent example is *Myrica faya*, an invader of volcanic soils in Hawai'i (Vitousek and Walker, 1989). The rate of nitrogen fixation of *M. faya* is two orders of magnitude higher than that of associated native species, leading to overall increases in nitrogen availability at the ecosystem level. Such processes can also facilitate invasion by other nonnitrogen-fixing species, such as the stimulation of *Bromus diandris* growth in soil obtained from patches of the invasive nitrogen-fixing shrub *Lupinus arboreus*. Other NIPS alter soil chemistry through salt concentration or produce allelopathic chemicals that negatively impact on native species.

Morphological and physiological differences between NIPS and associated native species can also alter the spatial and temporal distribution of water through the soil profile, in turn affecting ecosystem composition and structure. Grasses such as *Pennisetum setaceum*, an invader of tropical dry forests in Hawaii, can reduce water availability in the upper rhizosphere, in turn reducing the health of coexisting native tree species (Cordell and Sandquist, 2008). In contrast, deep-rooted woody or taprooted species can alter soil water balances by drawing water from deeper in the soil profile, changing subsoil drainage patterns and patterns of primary production. Differences in phenology can also be critical; for example, the displacement of the summer-active C4 species *Themeda australis* by the invasive spring-active C3 species *Nassella neesiana* is believed to have altered the timing of peak soil water availability in temperate grasslands and pastures of south-eastern Australia. Similarly, exotic species including the winter-active grass *Bromus tectorum* shift soil water extraction in semiarid shrub-steppe ecosystems in western North America to earlier in the growing season, reducing later availability for native species. Similar interference patterns occur in crops and pastures invaded by agricultural weeds.

At broader scales, NIPS can significantly alter ecosystem processes by changing nutrient pools, the flow of energy though plant communities, or the structure and behavior of entire food webs and trophic levels. One frequently observed effect of increased biomass production by invasive species is an increase in the size of above- and below-ground carbon pools, and associated fluxes. Carbon inputs are generated by plant net primary productivity, which is often, although not always, greater in invasive species, and litter produced by invasive species typically decomposes faster due to lower C:N ratios and lower lignin:N ratios in plant tissue. As noted previously, soil N pools and fluxes can be radically altered by invasive species, especially N-fixers, although significant changes have also been observed in response to invasion by grasses. Soil and plant respiration are the major pathways of

carbon loss in terrestrial systems, and these can also be altered by plant invasion, as can N loss via nitrification and denitrification. However, the magnitude and direction of these changes often vary significantly across different habitats and different invasive species, and more work is needed to determine whether any broad patterns can be discerned across invaded systems and species more generally.

One dramatic way in which invasive species can significantly alter both the structure and processes of entire ecosystems is by inducing change in fire regimes. Because plant species have multiple strategies for maximizing fitness in fire-prone habitats (e.g., resprouters vs. obligate seeders), changes in the timing, intensity, frequency, and extent of fires in response to elevated fuel loads have the potential to drastically change vegetation composition and structure. These changes to vegetation can in turn alter fire behavior in self-perpetuating positive feedback loops. An excellent example of such a process is the 'grass-fire cycle' in which high biomass production by invasive grasses results in hotter fires, which increases mortality in overstorey vegetation. This in turn allows further invasion, leading to the eventual replacement of savanna, woodland, or forest plant communities by grassland – a process that is occurring in northern Australia where savanna vegetation is being invaded by the highly productive Gamba grass (*Andropogon gayanus*). Interestingly, the high-severity fires generated by Gamba grass and associated loss of tree species significantly reduce above-ground carbon storage and may increase greenhouse emissions (Setterfield *et al.*, 2010), demonstrating the impact that invasive species can have on ecosystem processes that are critically important at the global scale.

The authors have discussed some of the direct and indirect mechanisms by which invasive plants can alter the composition and diversity of plant communities and the processes that structure entire ecosystems. NIPS, however, can also have profound genetic effects on native or agricultural species. One important mechanism involves the mixing of gene pools of formerly distinct taxa; in this context the authors are mainly concerned with hybridization and introgression between previously isolated native species and NIPS, known as genetic assimilation or genetic swamping (Antilla *et al.*, 1998). This process can potentially lead to extinction, especially if the native species is rare, and is of increasing concern to conservation biologists due to the high levels of sexual compatibility observed among plant species in general. Perhaps the best documented example is of sunflowers in North America, where introgression between weedy *Helianthus annuus* and rarer endemic species (e.g., *Helianthus bolanderi)* threatens the endemic species with local or even range-wide extinction. In the case of *H. annuus* and *H. bolanderi*, more recent introgression has led to the development of populations that are morphologically more similar to *H. annuus* (Carney *et al.*, 2000). This process can occur even if the invasive species is rarer relative to the native species, as is the case in *Spartina alterniflora* in California, which, due to high male fitness, threatens to assimilate the more widespread native *Spartina foliosa*. In this example, competition between *S. alterniflora* and *S. foliosa* pollen tubes is thought to favor *S. alterniflora* on the stigmas of both species, which is an interesting form of reproductive interference. Introgression can range from primarily unidirectional, as with gene flow from introduced Siberian elm (*Ulmus pumila*) to red elm (*Ulmus rubra*) in the eastern US, to bidirectional. Interestingly, recent studies indicate that biparental introgression can lead to the replacement of parental lineages by hybrid genotypes (e.g., California radish; *Raphanus* sp.), provided hybrids and hybrid descendents do not suffer from outbreeding depression. It should also be mentioned that hybridization can pose a threat to small plant populations even in the absence of introgression.

Genetic effects of NIPS on recipient plant communities and ecosystems are not restricted to those associated with gene flow and hybridization. For example, evolution can occur in other trophic groups, especially insects, in response to the establishment of novel plant populations, and the mixing of biota may lead to the generation of new kinds of mutualistic interactions that stimulate further coevolution (Mooney and Cleland, 2001). The dramatic decline in populations of native species in response to incursion by invasive species is likely to increase the probability of genetic drift, inbreeding, and other genetic consequences associated with population bottlenecks. Finally, given that many invasive plants differ in phenology and morphology from associated native species, shifts in the timing, severity, and resource specificity of competitive relations among native and exotic plants are likely to significantly alter the intensity and direction of selection, and hence evolution, in both groups.

Ecosystem Invasibility

The concept of 'invasibility,' which refers to the vulnerability of an ecosystem to invasion, arose in response to the basic observation that plant communities and biomes differ significantly in their tendency to be invaded by NIPS (Lonsdale, 1999). Explaining why this is so has been one of the most heavily researched areas in invasion biology. One commonly observed pattern is that invasions tend to be promoted by disturbance, fragmentation, high resource availability, and slow recovery of native vegetation, such that late-successional plant communities tend to be invaded by few NIPS compared with those that have been highly modified. As noted previously, a large proportion of invasive species worldwide can be classified as r-strategists, characterized by rapid growth and biomass accumulation and high reproductive potential, and these species tend to be favored by disturbance and high nutrient availability. It is therefore not surprising that disturbed or modified systems tend to be heavily invaded, and that so many agricultural systems suffer invasion by weedy species – both cropping and pasture-based agricultural systems create homogenous, highly modified environments characterized by high resource availability, low competition, and recurring disturbance. Indeed, disturbance-driven intermittent resource enrichment or release leading to differences between resource supply and resource uptake has been proposed as a general process that increases the susceptibility of plant communities to invasion by alien species.

The 'biotic resistance hypothesis' has long been advanced to explain why less disturbed systems tend to be less invaded

by exotic species. Competition with native species is well known to represent a major barrier to invasion, especially when resources are limited, because nonindigenous competitive advantage appears to be strongly linked to overall resource availability. Functional similarity between native and nonindigenous species can increase competitive interference, and based on associated niche-packing models it has therefore been argued that more diverse or species-rich native assemblages should be less invasible than impoverished ones. Indeed, depauperate communities may even contain vacant niches that allow preadapted species to readily establish invasive populations – *Ammophila arenaria* in Californian coastal dunes ecosystems is a frequently cited example. This has proved, however, to have been a contentious idea in invasion ecology, because the empirical data inconsistently show a negative relationship between native and exotic species diversity. Indeed, a frequently observed pattern is that native and exotic plant diversity tends to be negatively correlated at small spatial scales, due to competitive exclusion, but positively correlated at large scales, where differences in the diversity and availability of resources affect both native and exotic species in similar ways. The diversity of species and functional groups occurring within different trophic levels may also impact on community invasibility in some ecosystems.

Abiotic resistance is also seen as an important driver of invasibility. At the biome scale, for instance, deserts, savannas, and other harsh environments tend to be less invaded by exotic plants than more mesic habitats, the latter being more generally favorable for seedbank germination and seedling survival. However, these patterns also to some extent reflect the specific nature of the pool of nonindigenous species that are potential sources of invasive species – for example, some extreme environments face little 'propagule pressure' from species that are adapted to those conditions. This can arise from the history and composition of introductions in a given region, which reflect patterns of agricultural development, seed movement, ornamental plantings, and many other social and economic factors. An excellent example of this occurs in temperate south-eastern Australia, where numerous introductions have occurred through agricultural practices including the long-distance transport of seed and hay from other temperate areas. Given their provenance, these species are typically unable to survive in intact Australian alpine vegetation, which appears to be less invasible than lowland temperate ecosystems. However, pressure from species that are better adapted to such conditions is now also increasing, and it is likely that such systems will turn out to be more invasible than was initially suspected.

Collectively, these lines of evidence indicate that variation in the diversity and abundance of invasive plants in different habitats, which may at first glance be causally linked solely to invasibility, in fact reflects differences in species traits, characteristics of the recipient community, and propagule pressure. Untangling the interactions between these drivers will continue to be a focus of invasion biology research with capacity to improve our management of agricultural and natural landscapes in the face of an increasingly large pool of potentially invasive species.

Contemporary Issues in Invasion Ecology

Climate Change and Plant Invasions

There is now overwhelming evidence that anthropogenic emission of CO_2 is altering the climate of the earth. Over the past century global temperatures have risen by approximately 0.75 °C and it is estimated that 1.8–4.0 °C of warming (relative to 1980–99) is likely to occur by the end of the twenty-first century, depending on the emissions scenario. A major emerging concern is that future climate change linked to anthropogenic global warming (AGW) could increase the fitness of NIPS relative to native species, thus magnifying their impacts on natural and agricultural ecosystems.

There are very good reasons to suggest that many extant invasive NIPS will have an enhanced capacity relative to native species to respond to changes in abiotic and biotic stressors (Dukes and Mooney, 1999). To become successful invaders, all exotic species must pass through a series of environmental filters (**Figure 1**); those that fail to do so ultimately lack the ability to establish populations in new environments and undergo landscape-level spread. Barriers to success include geographical limits to colonization, abiotic limits to establishment and survival of founder populations, biotic limits to population expansion, and landcape-level limits to population spread. Only exotic plants that possess certain combinations of traits associated with dispersal, growth, competition, and adaptation can pass through these filters, and those that do tend to become widespread and abundant.

These filters select for successful invaders that contrast with native species in a number of key ways. First, most native species are rare or have restricted geographical ranges, whereas invasive species tend to have broad physiological tolerances to abiotic stress and occupy large ranges (Hellmann *et al.*, 2008). Rare species usually have slower population growth rates, lower competitive ability, and a reduced capacity to cope with abiotic and biotic change. Exotic species also often exhibit high levels of genetic diversity in their native range, which increases the chance of matching specific, locally adapted genotypes to climatic conditions of the invaded range (preadaptation). Opportunities for preadaptation are enhanced in exotic species with a history of multiple introductions, which has occurred in many of the worst ornamental and pasture weeds. A prime example is St. John's wort (*Hypericum perforatum*), which has been introduced into North American from Europe on multiple occasions, and which displays climate matching of source genotypes in the invasive range.

Populations of invasive species also frequently undergo rapid evolution, including for climate-related traits that increase fitness in new environments. Adaptive differentiation of populations along broad climatic gradients has been observed in many species, including purple loosestrife (*Lythrum salicaria*), invasive North American populations of which have developed strong latitudinally based clinal variation for phenological traits (flowering time and size at flowering time) that are similar to those that are found in native European populations. Other examples include ragweed (*Ambrosia artemisiifolia*), African ragwort (*Senecio inaequidens*), and sunflower (*Helianthus maximiliani*; Kawakami *et al.*, 2011). Adaptive evolution can also arise from the admixture of previously

separated and distinct genetic lineages and subsequent generation of novel genotypes, providing invasive species with added capacity to invade new habitats.

'Phenotypic plasticity' has also been suggested as a key driver of plant invasiveness, because having the ability to maintain positive population growth rates in a wide range of environments is likely to confer an advantage over more specialized native or crop species (Hulme, 2008). Enhanced niche breadth linked to phenotypic plasticity can be striking: Brazilian pepper (*Schinus terebinthifolius*), for example, a highly invasive species in the southern US, can grow as a tree, vine, or scrambling shrub, depending on growing conditions. Plasticity in reproductive allocation, dry matter partitioning, and growth have been observed in numerous crop and pasture weeds (e.g., *Echium plantagineum*; *Ammannia* spp.), and can alter competitive relationships among plants when grown under conditions of limited resource availability. By allowing plants to more efficiently exploit a wide range of environments and by compensating for the low genetic diversity that typifies many founder weed populations, phenotypic plasticity is also likely to place at an advantage plant populations subjected to increasing climatic variability or enhanced abiotic stress (Nicotra *et al.*, 2010).

Seeds produced by invasive NIPS often have specific morphological adaptations for wind, water, or animal dispersal that increase the rate and distance of propagule movement into new habitats (Murray and Phillips, 2010). For example, low seed mass often facilitates wind dispersal, while many ornamental species produce fruit that are spread long distances by birds and animals (zoochory). Some species have multiple modes of seed production: An excellent example is the invasive South American tussock grass *Nassella neesiana*, which produces seeds in panicles, stems, and at the base of the tussock. This gives *N. neesiana* the capacity to spread rapidly via multiple vectors (e.g., grazing animals, roadside mowing), and as a result it has become one of Australia's worst invaders of native grassland and grazed pastures. Rapid generation time, typical of many r-selected species, is another life-history adaptation that facilitates the growth and spatial expansion of plant populations. Shifting climatic envelopes are expected to benefit species that can rapidly extend populations into new climatically suitable ranges, and it is likely that many invasive species, especially those that are already efficient dispersers, will benefit.

One of the most often-cited differences between native and invasive NIPS is in competitive ability and overall growth and biomass production (Vilà and Weiner, 2004). Typically, invasive species have rapid growth rates, and numerous studies suggest that most are highly competitive in both natural and agricultural settings. However, in most circumstances the magnitude of any growth or competitive advantage enjoyed by invasive species depends on resource availability: in resource-poor environments native species often have superior or equal fitness (Daehler, 2003). In typical high-fertility cropping situations such conditions are unlikely to arise, but nutrient limitation often negatively impacts on the performance of exotic species in seminatural (e.g., unimproved pasture) and natural vegetation. In these environments, disturbance favors invasive species because it frees up resources that would otherwise be exploited by existing native vegetation. It is therefore clear that interactions between climate change and other drivers of global change (Marini *et al.*, 2012), including anthropogenic disturbance and habitat fragmentation, will determine the relative fitness of invasive species in the coming century.

Rising atmospheric carbon dioxide concentrations [CO_2] associated with the burning of fossil fuels is another driver of global change that will impact on all plant populations. Because trade-offs exist between acquisition of atmospheric CO_2 and water loss, altering [CO_2] changes physiological processes taking place in plant tissue, in turn altering plant growth and water use efficiency. Many invasive and native plants increase biomass production and fecundity under elevated [CO_2], a response known as the CO_2 fertilization effect (Godfree *et al.*, 2013). This process has been implicated in the success of a number of invasive species, including cheatgrass (*Bromus tectorum*) in semiarid rangelands of the US. However, although the high phenotypic plasticity of invasive species may increase their ability to shift their physiological optimum to take advantage of CO_2 fertilization, at present it appears questionable whether invasive species should in general disproportionately benefit more from rising [CO_2]. Indeed, a large proportion of the world's worst weeds are C_4 species, and many compete with C_3 crops, which in general tend to be more responsive to CO_2 fertilization.

Overall, developing a level of knowledge sufficient to answer the question of nonindigenous advantage under AGW with any certainty is likely to be a challenging task, especially given the somewhat chequered history of predicting the success of invasive species in general. Nonetheless, understanding the links between the traits and attributes of NIPS and key climatic drivers will underpin our ability to manage or avoid the detrimental impacts of NIPS on a global scale.

Transgenic Plants as Invasive Species

The impact of genetic modification (GM) or engineering on the biosafety of recipient organisms has been one of the most contentious issues in ecology of the past two decades (Hails, 2000). Genetic modification involves the transfer of genetic material (a transgene), usually coding for a beneficial trait, from one organism into a target organism (the genetically modified organism or GMO), which then expresses the trait. Since 1996 GM technology has been rapidly adopted across the globe, and in 2011 over 160 million hectares of GM crops were grown across 29 countries, a figure that is currently increasing at a rate of approximately 8% per year. A small number of widely grown species (cotton, corn, soybean, and canola) expressing herbicide tolerance (HT) and virus and insect resistance (VR and IR) still dominate global plantings of transgenic crops.

In the late 1970s to mid-1980s arguments were widely put forward that no GMOs should pose any risks to the environment. These were based on a range of premises, such as that genetic modification does not produce any genetic novelty that could not otherwise be generated by traditional selective breeding, or that all GMOs will suffer metabolic costs associated with transgene expression leading to reduced environmental fitness. This view, however, was challenged shortly

after when it became clear that genetic engineering had the potential to create truly novel combinations of potentially adaptive traits, especially where phylogenetic leapfrogging was involved. Pleiotropic or other unintended effects associated with the transformation process could also impact strongly on plant phenotype in unpredictable ways. Since then, the development and release of GMOs has been placed under strong regulatory oversight in most countries, and methods for quantifying risk associated with GMO deployment have been the focus of sustained scientific endeavor (Hilbeck *et al.*, 2011).

One of the most widely discussed potential risks associated with GMO release involves transgenic organisms or wild relatives becoming weedy either in crop or nontarget environments. This can occur via two main pathways (**Figure 2**): either the GMO itself can spread into nontarget areas outside of the cropping area and become invasive, or gene flow can occur into wild relatives growing in nontarget habitats, which then become invasive. For the majority of transgenic crops, the highest-risk situations occur when the transgene confers a clear fitness advantage under natural selection regimes and where hybridization with wild relatives is possible. Many transgenes are unlikely to increase the fitness of either crop plants or wild relatives in noncrop situations, for example, herbicide (glufosinate or glyphosate) tolerance in natural ecosystems. However, other traits such as pathogen or insect resistance could increase the fitness of plants containing the transgene significantly. Probably the most widely studied transgenic plants that fall into this category contain *cry* genes *Bacillus thuringiensis* (*Bt*) that express endotoxin proteins that provide resistance to insect pests.

Many crops such as maize and cotton that express *cry* genes are unlikely to become themselves invasive because they are highly domesticated and lack critical demographic traits that are essential for establishment of feral populations in nontarget environments, such as seed dormancy or the ability to compete with native vegetation for light, water, and nutrients. Of much greater concern in these crops is the potential for gene flow to wild relatives, a process involving pollen flow, the formation of viable wild-crop hybrids, and (usually), if the transgene present confers a selection advantage, gene introgression into wild populations (**Figure 2**). Given that virtually all the world's most important crops hybridize with wild relatives somewhere in the world (Ellstrand *et al.*, 1999), it seems virtually inevitable that gene flow from transgenic crops to wild relatives will occur, although this does not mean that a significant risk will be posed to the environment in all cases. Examples of GM crops in which the potential for hybridization with sexually compatible wild species or wild genotypes have been investigated include sorghum (with *Sorghum halapense*), maize (with teosinte), sunflowers, canola (with *Brassica rapa* and other species), sugar beet, and cotton (with other *Gossypium* species).

Transgenic pasture plants probably pose a greater invasive risk to the environment than most crop species because they have a wide range of traits that allow them to persist in mixed plant communities in which competition for limiting resources and abiotic stresses is more intense. Pasture species have a history of invasiveness, and many have shown the capacity to rapidly undergo range expansion and local adaptation following introduction. An increase in fitness arising from the presence of disease or pathogen- or stress-related transgenes in such species could therefore have serious consequences for nontarget plant communities. One of the best studied cases is that of virus-resistant white clover (*Trifolium repens*), which in south-eastern Australia, in addition to being an important pasture plant, is also an invader of endangered native grassland and woodland communities. Studies have shown that a range of viruses including *Clover yellow vein virus* limit the growth rate of wild *T. repens* populations, and thus the introgression of transgenes for virus resistance from sown pastures could increase the invasiveness of wild populations in these habitats (Godfree *et al.*, 2007). Another example is creeping bentgrass (*Agrostis stolonifera*), a highly competitive turf grass species. Flow of transgenes from HR genotypes to wild *A. stolonifera* populations and another related species, *Agrostis gigantea*, has been observed under field trial conditions, potentially making their control in other agronomic settings more difficult.

Ecological and evolutionary processes associated with the use of GM technology can also lead to weed problems within agricultural settings. GM plant lines can themselves volunteer in subsequent crops, especially if they produce a persistent seedbank. This is of particular concern in farming systems that rely on sequential rotations of crops that all express the same type of HT (e.g., glyphosate tolerance). Gene stacking can also lead to the development of plant lines resistant to multiple herbicides, as has been demonstrated in canola in Canada. Evidence suggests that the repeated use of a single herbicide group for control of weeds in GM crops can also lead to the development of herbicide-resistant crop weed biotypes, for example, Roundup resistance in *Conyza canadensis*. Both situations have significant implications for farm management and economics. Finally, the use of GM technology allows for greater control of weeds, but this may adversely affect other faunal associates that depend on plant biodiversity as a resource.

Over the past two decades, increased regulation of GMOs around the world has necessitated the development of new strategies for quantifying the potential direct and indirect risks posed to human health and the environment. Risk is defined by the equation risk=f(hazard, exposure) (Wilkinson *et al.*, 2003), where the hazard is the severity of the unwanted change and exposure is the probability of the hazard occurring. In the scenarios described above, hazard refers to the severity of the impact of increased invasiveness of GM crops or associated wild relatives on natural or agricultural systems. Hazards are normally identified using structured hazard identification studies in which potential scenarios leading to hazard realization are identified; several such scenarios are shown in **Figure 2**. In most cases, the efficacy of the genetic transformation and the potential impact of GM plants on target and nontarget organisms are initially evaluated by direct comparison of transgenic lines with genetically similar or identical isolines so that the impact of the introduced trait on plant phenotype and fitness can be directly quantified. Detailed 'exposure studies' are then conducted to determine the probability of each step in a given hazard scenario occurring following release of a transgenic plant into the environment. Risk assessments are often conducted in a carefully structured tiered procedure in which hazards are first indentified under

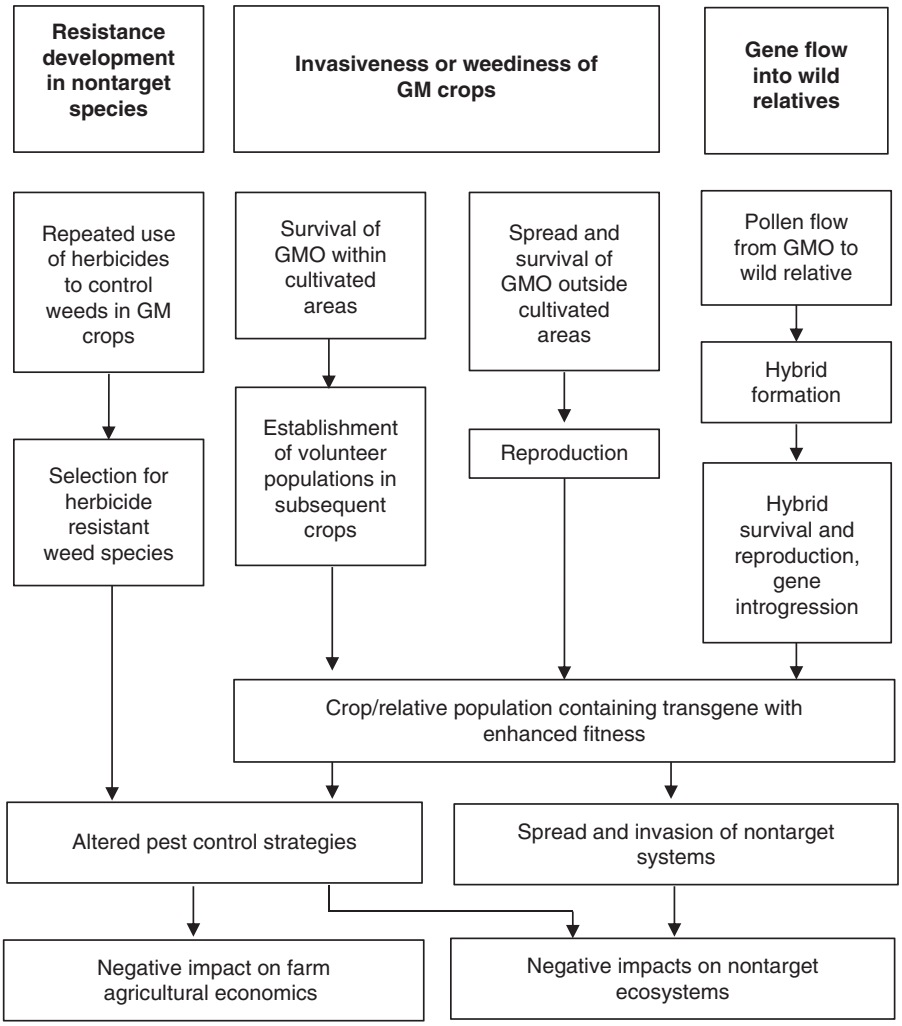

Figure 2 Framework for identifying some possible invasion hazards (bold) to nontarget and agricultural systems associated with the release of transgenic plants into the environment. Potential direct and indirect pathways leading to realization of hazard are shown; the risk assessment processes seek to quantify the probability of each stage in the hazard pathway occurring. Adapted from Sanvido, O., Romeis, J., Bigler, F., 2007. Ecological impacts of genetically modified crops: Ten years of field research and commercial cultivation. Advances in Biochemical Engineering-Biotechnology 107, 235–278.

'worst-case scenario' conditions using first-tier laboratory experiments and then more detailed second- and third-tier semifield and field experiments aimed at refining probabilities associated with specific steps within a given hazard scenario.

The combined experience from the past two decades suggests that the relatively small number of mainly herbicide-tolerant and insect- or pathogen-resistant GM crop species currently grown on a wide scale pose only a limited direct threat as invasive species. Although gene flow to weedy relatives will occur in some species, there are few examples to date of where this has led to realization of hazard in nontarget systems. However, a wide variety of 'new generation' GM crops engineered for oil and pharmaceutical production, drought tolerance, fungal resistance, altered phenology, bioremediation, and many other traits are also now in development or commercial adoption worldwide. Interactions between these plants and nontarget species and ecosystems are certain to be complex, and risk assessments that explicity test for increased invasiveness under field conditions will remain central to their successful, hazard-free release into the environment.

Using the Past to Inform the Future

Directions for Study and Management of Invasive Species in a Changing World

As this article has shown, invasion ecology is a dynamic, rapidly evolving field of research that continues to provide novel insights into the ways in which plants establish and maintain viable populations in new habitats and how they impact recipient agricultural and natural systems. Yet, many questions remain, and new approaches are being developed to better understand the role of plant invasions of agents of global change. For example, very recently, a small number of studies in invasion ecology have examined historical patterns

of introduction of invasive NIPS to particular regions of the world. Such comparative analyses of NIPS introductions can pinpoint periods in history when different regions of the world have received particularly high numbers of species. Such knowledge can provide an important historic baseline for determining the factors driving the successful spread of NIPS. An understanding of temporal introduction patterns can inform management aimed at limiting the ecological, economical, and social impacts of invasive NIPS on native biodiversity. Such a historical approach is somewhat analogous to using historical information on climate variation to predict future climate scenarios.

Australian work in this context has revealed distinct peaks since permanent European settlement of the continent began in the late 1700s. Peaks during early European settlement (1810–20) and human range expansion across the continent (1840–60) both coincided with considerable growth in Australia's human population. It is likely that human population growth during these times increased the likelihood of NIPS becoming invasive as a result of increased colonization and propagule pressure. Although this sort of research is in its infancy, there are many promising avenues to pursue, and valuable information to be gleaned from better understanding previous temporal patterns of NIPS introductions. Hopefully, such approaches will further increase our ability to predict and manage the impacts of NIPS globally in years to come.

Glossary

Benefit–cost ratio The ratio of the discounted present value of a stream of research benefits relative to the associated stream of research costs.

Internal rate of return The discount rate that equates the present value of the stream of research benefits and the present value of the stream of associated research costs.

Modified internal rate of return The compounding rate of interest that equates the future value of the stream of research benefits and the present value of the stream of associated research costs, given a particular value for the external rate of return on reinvested flows of benefits and a particular value for the rate of interest paid on borrowed funds.

Research and development expenditures Comprise expenditures on creative work undertaken on a systematic basis to increase the stock of knowledge and its use to devise new applications.

Research and development (R&D) spillovers The benefits conferred on a given geopolitical entity (e.g., a state or nation) from research conducted elsewhere.

Research intensity The ratio of national expenditures on public R&D relative to a measure of the corresponding value of output (often denominated as the value of agricultural gross domestic product).

Stock of knowledge An estimate of the accumulated stock of scientific knowledge currently in use, usually denominated in dollars of constant purchasing power.

Introduction

For most of farming's 10 000-year history, progress in agriculture was largely by trial and error, sometimes involving serendipity, other times involving astute observation, tinkering, and experimentation by farmers. This produced some gains in crop yields over the long haul but at a much slower pace than has been evident in recent decades (e.g., it appears that English wheat yields increased more than 15-fold during the past 800 years: beginning at approximately 0.5 tons ha^{-1} in the first half of the thirteenth century (Stanhill, 1976) to 3.5 tons ha^{-1} in 1961, and averaging 7.7 tons ha^{-1} in 2011 (FAO, 2013). Approximately 80% of the increase occurred in the past 200 years, with more than half of the increase occurring since 1961, although rates of gain in the UK wheat yields have slowed dramatically since the early 1990s). For much of this history, increases in crop production came mainly from increasing the land used in agriculture. This did not mean innovation was absent. Expanding the physical footprint of agriculture meant changing the agroecological attributes (soils, terrain, temperature, rainfall, and so on) that affected agricultural production, so simply to maintain average yields farmers had to scout, trial, and choose varieties of crops (or the crops per se) best adapted to these changed local circumstances (Olmstead and Rhode, 2002; Beddow and Pardey, 2014).

Scientifically bred crop varieties and livestock breeds, and their associated agricultural management practices, have a history of barely 100 years. In the middle of the nineteenth century and especially at the beginning of the twentieth century, a number of important changes occurred. Specifically, Darwin's theory of evolution, the pure-line theory of Johannson, the mutation theory of de Vries, and the 'discovery' of Mendel's laws of heredity all contributed to the rise of plant and animal breeding in the beginning of the twentieth century (In 1900, the Dutch botanist Hugo de Vries, the German botanist Correns, and the Austrian agronomist Tschermark independently and about the same time published studies on the laws of heredity that had been anticipated in the 1866 paper by the Austrian monk Gregor Mendel. When Mendel's paper was published in the *Proceedings of the Natural History Society of Brünn*, it had little impact and was cited very few times over the subsequent 35 years.). The mid-nineteenth century work of organic chemists like von Leibig led to substantial improvements in the understanding of the role soil fertility plays in plant growth (Von Liebig's book Organic Chemistry in Its Application to Agriculture and Physiology published in 1840 in both Germany and Great Britain triggered widespread interest in the application of science to agriculture. Within 8 years of its publication, von Liebig's book had gone through 17 different editions, translations, and revisions, mostly in Germany, England, France, and the United States but also in Denmark, Italy, the Netherlands, Poland, and Russia (Rossiter, 1975; Russell, 1966; Salmon and Hanson, 1964). Like others, Ruttan (1982) viewed von Liebig's book as the critical dividing line in the evolution of modern agricultural science.). Pasteur's germ theory of disease, together with other fundamental insights gained from bacteriology, virology, and related microbiological sciences, spurred the development of animal vaccines and more broadly promoted the development of methods to manage and mitigate production losses associated with crop and livestock diseases. Along with genetic innovations, this growing body of scientific

 doi:10.1016/B978-0-444-52512-3.00045-0

knowledge fostered a host of other innovations in pest and disease management, animal husbandry, and the like, which accompanied 'labor-saving' innovations that augmented and replaced human labor with wind and water mills and livestock draft power with tractors and other machines.

Organized research is itself a relatively recent innovation and has been an element of public policy for less than 200 years (Ruttan and Pray, 1987). Similarly, intellectual property rights (IPR) have existed in some form for centuries, but effective patents and patent-like rights have been formalized only relatively recently in most countries (e.g., in 1790 in the United States). Extending the scope of intellectual property (IP) protection to include the biological innovations used in agriculture is an even more recent phenomenon (Wright and Pardey, 2006).

Investments in agricultural research – irrespective of whether it is research conducted by private firms or public entities – now account for the lion's share of the technical progress in agriculture. However, it still takes a considerable time (typically decades not merely years) for the agricultural productivity consequences from investments in research to be fully realized. For this reason, this article presents and interprets new data on agricultural research and development (R&D) investments over the past half century, highlighting the changing public sector versus private sector roles. Research in the general biological sciences, genomics, informatics, and other sciences also affects progress in the food and agricultural sectors; so the article begins with a consideration of the changing global structure of overall investments in R&D.

International agricultural R&D and technology spillovers have long played important growth-promoting roles in agricultural economies around the world. The cost of communicating new ideas and tapping into technologies developed elsewhere in the world has been falling rapidly, such that access to other people's knowhow and innovations could well play an even bigger role in promoting future growth in agricultural productivity than in the past, both absolutely and relative to investments in homegrown R&D. With this in mind, this article presents measures of the potential for countries to tap scientific knowledge developed elsewhere in the world for the furtherance of their own agricultural sectors.

Finally, agricultural R&D pays handsome dividends. The article ends with a discussion of the evidence from hundreds of benefit–cost studies of returns to agricultural R&D and what it all means. It concludes that the evidence should be interpreted with care – the most common statistics quoted are likely to be misleading – but that there can be no doubt that the returns have been remarkably high in the past, a clear indication of an underinvestment from the point of view of the broader society, and there is no reason to think that the returns will be lower looking forward.

Investments in Science Worldwide

(This section draws heavily on Dehmer and Pardey (2014a).). Increasingly, innovations – in areas like genomics or precision agriculture and other informatics technologies – that affect agricultural productivity arise from R&D done in or for sectors other than agriculture. To place food and agricultural R&D in this broader innovation landscape the article begins with a brief look at the changing structure of science spending worldwide over the past three decades (Unless otherwise stated, throughout this article research expenditures in current, local currency units were first deflated to base year 2005 using country-specific implicit gross domestic product (GDP) deflators from the World Bank (2012) and United Nations (2011). The resulting series in constant currency units were then converted into 2005 international purchasing power parity (PPP) conversion factor dollars using the corresponding PPP from the World Bank (2012) and Heston *et al.* (2012). See Pardey *et al.* (1992) for an assessment of this approach.)

Dehmer and Pardey (2014a) estimated that the world spent a total of US$1.1 trillion (2005 PPP prices) on all types of public and private R&D in 2009 (For consistency with the reported global food and agricultural R&D totals to follow, spending by the eastern European and Former Soviet Union countries has been excluded from this 'world' total. In 2009, R&D spending by these countries was estimated to be approximately US$44 billion (2005 PPP prices).). This is roughly a threefold increase in (inflation adjusted) total R&D spending worldwide since 1980. Yet the global divide in this spending is stark. Eighty-one percent of the world's 2009 science spending was performed in just 10 countries, with the United States alone accounting for almost 33% of the world total (**Figure 1**). The 152 remaining countries of the world accounted for the remaining 19% of global spending. Notably, the middle-income countries of Brazil, India, and China (the BICs) are among the top 10 countries in terms of R&D spending and accounted for 17% of the world's 2009 total. The low-income countries (those 32 countries with gross national income (GNI) per capita averaging less than US$1005 per person and striving to support 11.7% of the world's population) accounted for a mere 0.26% of the world's science spending in 2009 (Low-, middle-, and high-income designations are based on the World Bank (2011).). To underscore the magnitude of these spending differences, in 2009 the high-income countries invested US$840 per person (2005 PPP prices) in R&D, whereas the middle-income group spent US$52 per person and the low-income group committed just US$4 per person.

The large economic disparities in the distribution of investment in R&D are plainly evident in **Figure 1**. China, a lower middle-income country, by 2009 accounted for 12.6% of the world's R&D spending in that year. The rest of Asia and Pacific (including India) had a global market share of just 3.4% – about the same share as Latin America and Caribbean (including Brazil) – whereas sub-Saharan Africa (where, of the countries for which R&D data are available, 47 are low-income countries) accounted for less than 1% of the world total.

Although the United States and other high-income countries still make up by far the largest share of global science spending, there are signs of an inexorable shift in the global R&D landscape. Growth in real spending from 2000 to 2009 in high-income countries, at just 3% per year, was the lowest of all income groups. Spending in low-income countries grew by 8.4% per year during this same period (albeit from a small base), whereas real R&D expenditures in middle-income countries grew by a remarkable 12.4% per year.

Approximately 66% of the world's R&D was done by private firms in 2009, with an especially marked concentration (81%) of that private research being performed in rich

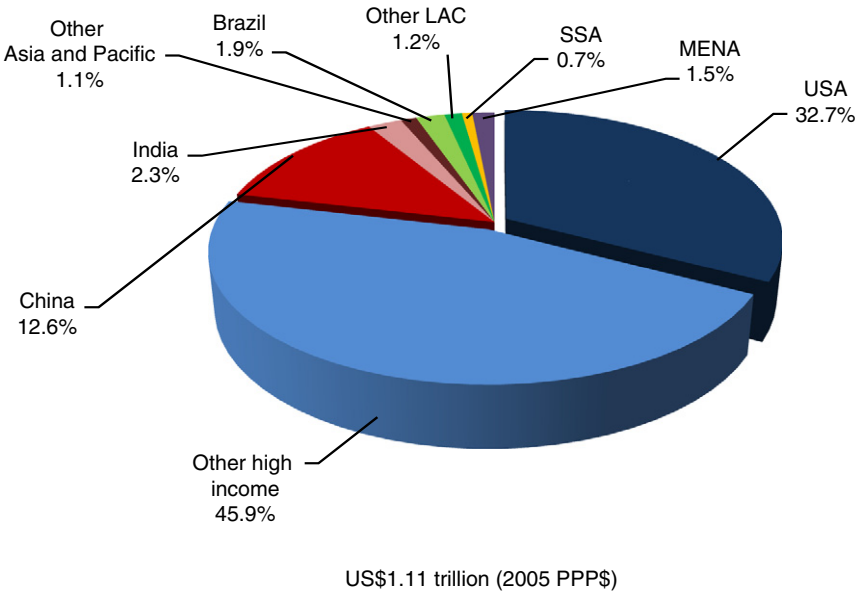

Figure 1 The geography of R&D spending worldwide, 2009. LAC, Latin America and Caribbean; MENA, Middle East and North Africa; PPP$, purchasing power parity conversion factor dollar; SSA, sub-Saharan Africa. Data include private and public spending estimates for 162 countries. Eastern European and Former Soviet Union countries are excluded. Reproduced from Dehmer, S., Pardey, P.G., 2014a. 'Global science spending, 1980–2009.' International Science and Technology Practice and Policy (InSTePP) Center Report. St Paul, MN: University of Minnesota.

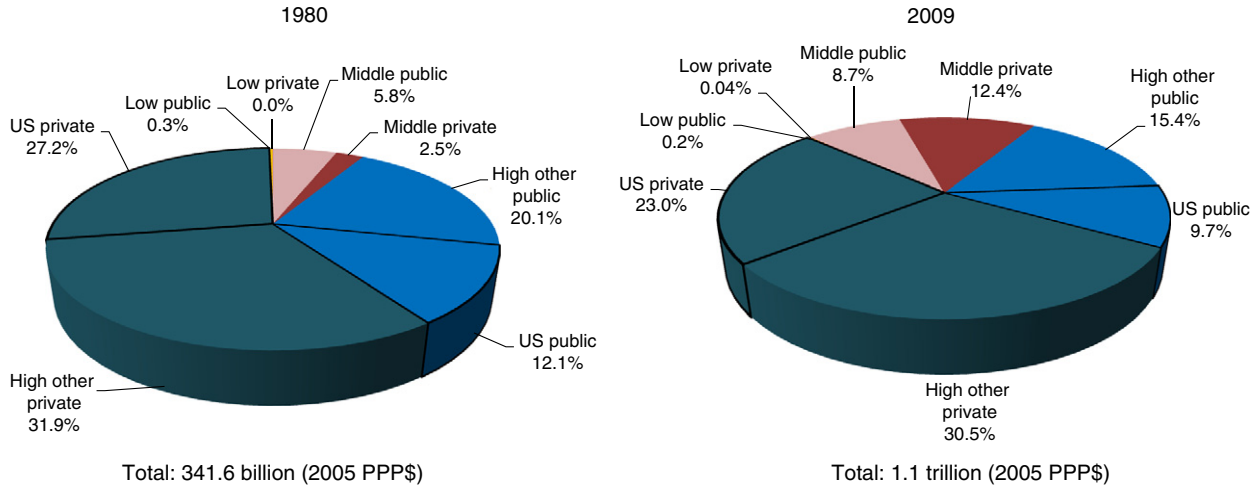

Figure 2 Global public and private R&D spending, 1980 and 2009. PPP$, purchasing power parity conversion factor dollar. Eastern European and Former Soviet Union countries are excluded. Countries are grouped into income classes using contemporary World Bank schema. High-income countries are those with 2010 GNI per capita of US$12 276 or more; middle-income countries had 2010 GNI per capita between US$1006 and US $12 275; and low-income countries had 2010 GNI per capita less than or equal to US$1005 (World Bank 2011, p. 389). Reproduced from Dehmer, S., Pardey, P.G., 2014a. 'Global science spending, 1980–2009.' International Science and Technology Practice and Policy (InSTePP) Center Report. St Paul, MN: University of Minnesota.

countries (Figure 2). Consequently, private sector research accounted for 68% of the total research spending in high-income countries, compared with 58% in the rest of the world.

Agriculture accounts for a modest share of total R&D. In 2009, global total (public and private) investments in food and agricultural R&D were approximately US$53 billion (2005 PPP dollars), just 5% of the overall science spending in that year (This estimate assumes that 90% of the world's 2009 private food and agricultural R&D spending occurred in high-income countries. See Section Private Sector Food and Agricultural R&D below, and especially Dehmer and Pardey (2014b) and Pardey and Chan-Kang (2014).). Nonetheless, that investment has realized demonstrably high returns (see Section Conclusion below) and is undergoing significant

changes in terms of where in the world that research is being carried out and who performs it. These changes could well have profound consequences for the nature and pace of innovation and productivity growth in global agriculture over the decades ahead, and it is to these investment trends the article now turns its attention.

Private Sector Food and Agricultural Research and Development

(This section draws heavily on Dehmer and Pardey (2014b) and Pardey and Chan-Kang (2014).). Although the empirical handle on private investments in food and agricultural research worldwide is far from certain, the available evidence indicates that the private share of global food and agricultural R&D is in the 35–41% range (Pardey and Beintema (2001; **Table 2**) estimated that the private share of global agricultural R&D was almost 35% in c. 1995, and approximately 94% of that research occurred in developed countries. Beintema and Stads (2008) (**Figure 4**) put the private share of the total at 41% in 2000, of which 94.4% took place in high-income countries. Fuglie *et al.* (2011, Table 1.2) estimated the private share of total to be 39% in 2000, with the high-income country share of global private food and agricultural R&D being 89%.). Like R&D in general, the lion's share of food and agricultural R&D (estimated to be in the 89–94% range) takes place in the high-income countries. The limited private sector participation in agricultural research done in or for developing countries stems from several factors, many of which are likely to persist for some time (except perhaps in countries experiencing relatively rapid economic growth, such as Brazil, China, and India). A significant share of food produced in developing countries is consumed by the household that produced it. Even when commodities enter the marketing chain, in developing countries they are often purchased in less-processed forms for preparation and eating at home. Consequently, a much smaller share of the food bill in developing countries accrues to postfarm food processing, shipping, and merchandising activities, areas where the incentives for private innovation are relatively pronounced.

Likewise, on the supply side, purchased inputs (such as herbicides, insecticides, improved crop varieties or animal breeds, and all sorts of agricultural machinery) constitute a comparatively small share of the total costs of production in many agricultural market segments in many parts of the developing world. Although this is likely to change as incomes rise and infrastructure improves, the pace of change will likely be uneven and more gradual in the poorest areas where (semi-) subsistence farming still predominates. The cost of doing business in places with small and often remote farms subject to poor market access, lack of farm credit, and limited communication services also undercuts private participation in agribusiness, in turn reducing the private incentives to invest in R&D targeted to these markets. In addition, a plethora of regulations, many times inefficiently enforced, combined with an uncertain and incomplete legal environment (especially related to contract law and intellectual property protection) make it difficult for local and multinational private interests to profitably penetrate agricultural markets with new seed, chemical, or other agricultural technologies in substantial parts of the developing world.

These many impediments notwithstanding, private investment will be critical to agricultural development and increased productivity in important parts of the developing world. However, the current obstacles to investment make clear the importance of public investments, which can make private investment in these areas more attractive. Publicly performed R&D continues to play a pivotal, and typically complementary, role to private R&D in the rich countries and will remain the principal if not sole source of agricultural innovations for many of the world's (poorer) farmers for many years to come.

Rich-Country Trends

Approximately 90% of the world's private food and agricultural R&D is performed in rich countries. Pardey and Chan-Kang (2014) reported that privately performed food and agricultural R&D in rich countries grew from US$4.3 billion (2005 PPP prices) in 1970 to US$17.5 billion in 2009, an average real rate of growth of 3.7% per year (**Figure 3**, inset) (The countries in this rich-country grouping include Australia, Austria, Belgium, Canada, Denmark, Finland, France, Germany, Greece, Iceland, Ireland, Israel, Italy, Japan, the Netherlands, New Zealand, Norway, Portugal, the Republic of Korea, Spain, Sweden, Switzerland, the United Kingdom, and the United States.). The spatial concentration of this research is also especially pronounced. Just two countries, the United States and Japan, accounted for more than half (55%) of this rich-country private food and agricultural total in 2009, with the top five countries (also including France, Germany, and the United Kingdom) accounting for three-quarters of the corresponding spending total.

The growth in private food and agricultural R&D spending in rich countries was faster than the corresponding real rate of growth of public sector spending among these countries (which averaged 2.1% per year for the period 1970–2009), such that the average ratio of private to public spending increased from 0.62 in 1970 to 1.08 in 2009. The drift toward an increasing share of food and agricultural R&D being performed by private firms was fairly widespread: 79% (19 of 24 rich countries) had higher private-to-public spending ratios in 2009 versus 1970. However, in only 11 countries did private food and agricultural R&D spending in 2009 exceed public spending (compared with five countries in 1970) – ranging from 87% of the food and agricultural R&D total in Switzerland to 50% in Japan. In 2009, the private share of total spending averaged 34% for the remaining 13 rich countries, with Greece having the smallest private share at 11%.

There is a tendency to think of private food and agricultural R&D as being mainly investments in research on agricultural chemicals, crop breeding, and machinery. Important as those areas of innovation are, research targeted to the food, beverages, and tobacco subsector accounted for 46% of the rich-country private food and agricultural R&D total in 2009 (**Figure 3**). The share of food, beverages, and tobacco R&D has shrunk a little over the past four decades (from 53% of private food and agricultural R&D in rich countries in 1970), and this

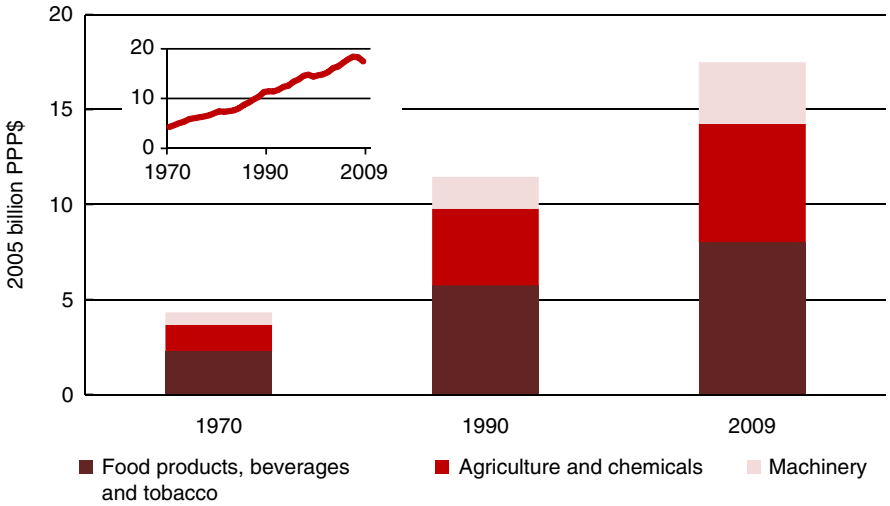

Figure 3 Private food and agricultural R&D in the rich countries, 1970–2009. PPP$, purchasing power parity conversion factor dollar. There are 24 countries included in the total presented. They are Australia, Austria, Belgium, Canada, Denmark, Finland, France, Germany, Greece, Iceland, Ireland, Israel, Italy, Japan, the Netherlands, New Zealand, Norway, Portugal, the Republic of Korea, Spain, Sweden, Switzerland, the United Kingdom, and the United States. Inset plots real annual spending from 1970 to 2009. 'Chemicals' and 'machinery' represent estimates of agriculturally related chemicals and machinery research, respectively. 'Agriculture' includes crop breeding and other areas of research of relevance to production agriculture. Reproduced from Pardey, P.G., Chan-Kang, C., 2014. Public and private R&D for food and agriculture in rich countries, 1960–2009. InSTePP Report. St Paul, MN: University of Minnesota.

trend is evident in 15 of the 24 rich countries in Pardey and Chan-Kang (2014).

These overall shares of rich country spending mask substantial cross-country differences in the orientation of their private food and agricultural R&D investments. For example, in Ireland and Portugal, food, beverages, and tobacco R&D accounted for more than 80% of the private food and agricultural R&D total in 2009, whereas in Sweden, Germany, and Austria more than two-thirds of private agricultural R&D was focused on machinery, agriculture (including crop breeding), and chemicals-related research.

United States Developments

Like many other rich countries, the United States has a long history of private innovation in agriculture and public policies to incentivize private R&D effort. The introduction of IPR, beginning in the United States with patents, trademarks, and copyrights in the eighteenth century, rates among the more prominent public policy measures intended to stimulate the creation and dissemination of US inventions. Many of the agricultural patents in the middle of the nineteenth century dealt with agricultural machinery, implements, and devices. Even something as seemingly simple as farm fencing material was heavily patented. Beginning with patent number 63,482 issued on 2 April 1867 to Alphonzo Dabb from Elizabethport, New Jersey for 'Improvement in Pickets for Fences and Walls,' more than 400 patents were issued for designs and manufacturing methods related just to barbed wire (Clifton, 1970; Krell, 2003).

In the United States, as elsewhere in the world, changes in the scope of intellectual property protection have been associated with a rise in agricultural innovations coming from the private sector. For example, legal forms of plant varietal rights have been on offer in the United States since 1930 and the private sector share of the rights issued has risen from 55% in the 1930s and 1940s to 82% of the rights in more recent times (Pardey *et al.*, 2014a). The intellectual property landscape evolved hand in hand with important changes in the genetics and genomics sciences that support crop varietal development.

Dehmer and Pardey (2014b) estimate that in 2009, US $6.8 billion of privately performed research was conducted in the United States directed toward food and agriculture (including forestry), compared with a total in 1950 of just US $67.9 million (US$463.5 million in 2005 prices) (**Figure 4**, inset). This implies an annual average rate of growth in private food and agricultural R&D of 9.0% per year over the period 1950–2009 or 4.9% per year when deflated by the implicit GDP deflator. The highest sustained real rate of growth (6.6% per year) was realized in the period 1950–80, a period of correspondingly rapid growth in public investment in agricultural R&D. Real growth slowed during the 1980s and early 1990s but picked up pace during the latter part of the 1990s (7.7% per year during the period 1993–98) as large agricultural chemical, machinery, and food companies ramped up their investments in agricultural research in the United States, along with a substantial number of smaller, new entrants (King, 2001; King and Schimmelpfennig, 2005). Private food and agricultural R&D spending declined immediately thereafter – from US$5.2 billion (nominal dollars) in 1998 to US$4.6 billion in 1999 – a prelude to the more general reduction in private research spending overall. It then recovered (even after adjusting for inflation) beginning in 2001.

Food, beverages, and tobacco research conducted by companies, including Kraft, Kellogg, and PepsiCo, is the largest category of private food and agricultural research in the United

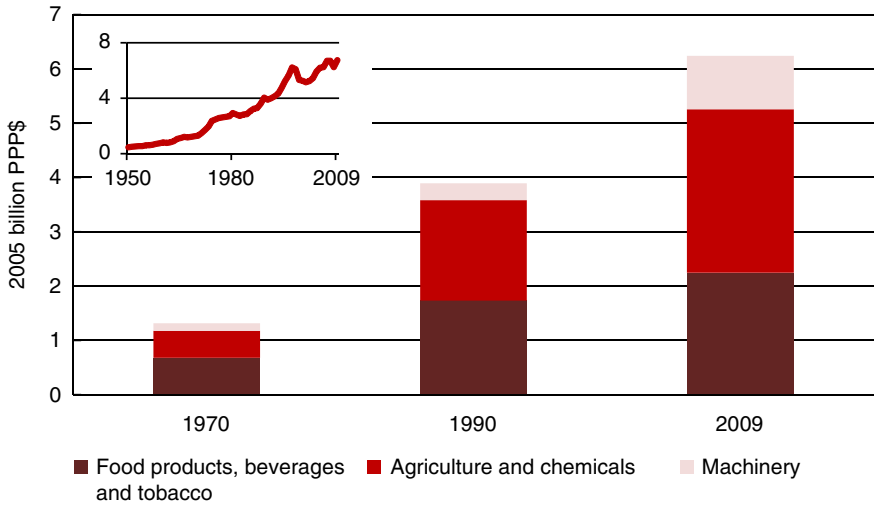

Figure 4 US private food and agricultural R&D, 1950–2009. PPP$, purchasing power parity conversion factor dollar. Inset plots real annual spending from 1950 to 2009. 'Chemicals' and 'machinery' represent estimates of agriculturally related chemicals and machinery research, respectively. 'Agriculture' includes crop breeding and other areas of research of relevance to production agriculture. Reproduced from Dehmer, S., Pardey, P.G., 2014b. 'U.S. private food and agricultural R&D spending, 1950–2009.' International Science and Technology Practice and Policy (InSTePP) Center Report. St Paul, MN: University of Minnesota.

States, accounting for 36% of the 2009 total. With 84.5% of the value of 2011 US food sales accruing to postfarm activities, this is to be expected (USDA, ERS, 2013) (Moreover, between 1939 and 2011, food consumed away from home rose from 19.2% to 48.7% of total US food expenditures (USDA, ERS, 2012).) Agriculture and chemical research (which includes biological research intended to develop new crop varieties as well as innovations designed to develop new herbicides, pesticides, fungicides, and veterinary medicines) account for the next largest share of private research, followed by research on new agricultural machinery and equipment.

Public Sector Food and Agricultural Research and Development

Important as private agricultural R&D has been, for much of the world the greatest part of the agricultural R&D effort that drove farm productivity growth was in the public domain. The public sector will likely continue to play a pivotal role, both as a complement to private R&D and as a substitute for private research in areas that lack the incentives for a sufficient private presence. A long-run perspective on investments in publicly performed R&D is presented here.

Trends in National Spending

(This section draws heavily on Pardey *et al.* (2014b,d), whose data were compiled in accordance with the guidelines spelled out in Organisation for Economic Cooperation and Development (OECD) (2002). Earlier compilations of global public food and agricultural R&D spending include Evenson and Kislev (1975a,b, Appendix 1), who reported research and extension expenditure and personnel estimates for 84 countries for c. 1965; Oram and Bindlish (1981), who developed annual agricultural R&D expenditure estimates for 51 developing countries for the period 1970–80; Pardey and Roseboom (1989), who reported a documented series of R&D spending and (full-time equivalent) personnel employed by national agricultural research systems (NARSs) that includes data on 154 developed and developing countries spanning the period 1960–86; and Beintema *et al.* (2012), who summarized estimates for 179 countries for the period 1980–2008. See also Pardey and Beintema (2001); Pardey *et al.* (2006) and Beintema and Stads (2008).). Over the past half century, and especially during the past decade or so, the global structure of public agricultural R&D spending has undergone a seismic shift. In 1960, just US$5.37 billion (2005 PPP prices) was spent on nationally conducted public agricultural R&D worldwide (**Figure 5**). By 2009 that total had climbed to US $33.6 billion: an average rate of (inflation adjusted) growth of 3.4% per year (Pardey *et al.* (2014b) reported an estimate for public agricultural R&D conducted in the Former Soviet Union (FSU) and Eastern European countries of US$1.14 billion (2005 PPP prices) in 2009. This figure includes estimates for the Czech Republic, Hungary, Poland, Romania, the Russian Federation, and 23 other countries from this region.). Big, and of late accelerating, geographical shifts in the location of performance of this R&D have been seen. In 1960 the high-income countries – classified according to average per capita incomes in 2009 (World Bank, 2011) – accounted for 56.2% of the world's total spending by national agencies: almost 50 years later, in 2009, that share had dropped to 48.5%. The United States has lost significant global market share, accounting for 21.5% of the worldwide total in 1960 but just 13.4% in 2009. If recent trends continue, the US position will continue to shrink. Pardey *et al.* (2014c) showed that the growth in real public sector agricultural R&D spending (i.e., intramural spending by the United States Department of Agriculture, USDA, and the state agricultural experiment

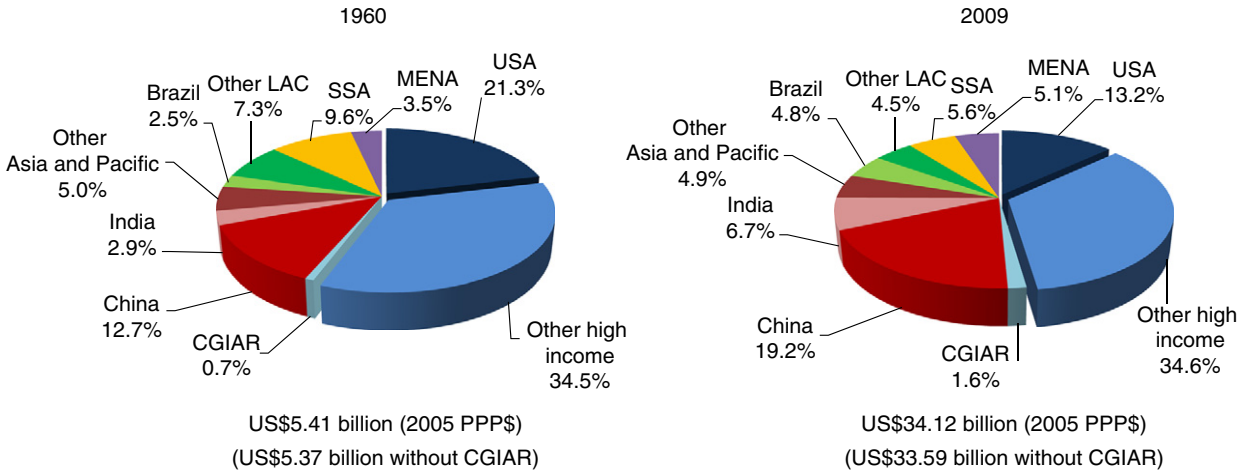

Figure 5 Structure of public food and agricultural research worldwide, 1960 and 2009. LAC, Latin America and Caribbean; MENA, Middle East and North Africa; PPP$, purchasing power parity conversion factor dollar; and SSA, sub-Saharan Africa. These estimates are for 126 countries, excluding countries from Eastern Europe and the Former Soviet Union. High-income countries are excluded from each geographical region. For example, Asia and Pacific excludes Japan and Singapore; MENA excludes Qatar and the United Arab Emirates. Reproduced from Pardey, P.G., Chan-Kang, C., Dehmer, S., 2014b. Global food and agricultural R&D spending, 1960–2009. InSTePP Report. St Paul, MN: University of Minnesota.

stations) has transitioned from an extended period of slowing down to one of no growth or negative growth (Using the implicit price deflator for GDP to adjust for inflation (as is done for almost all of the R&D data reported in this article) indicates that real spending on publicly performed agricultural R&D in the United States has flatlined since 2004. Using a purpose-built US agricultural R&D deflator (which grew at an annual average rate of 3.83% per year from 2004 to 2009, compared with 2.61% per year growth for the implicit GDP deflator) indicates a cut back in real spending since 2004.).

Sub-Saharan Africa has also lost market share, declining from 10% of the world's total in 1960 to 6% in 2009. So too has the Latin America and Caribbean region; although Brazil's share increased from 3% to 5%, the rest of that region lost ground relative to the rest-of-the-world aggregate. The notable expansion in market share was in the Asia and Pacific region: China's share grew from 13% in 1960 to 19% in 2009, whereas India's grew from 3% to 7%. In 2009, 31% of the world's public agricultural R&D took place in the Asia and Pacific region compared with just 21% in 1960.

Figure 6 plots the trends in real spending from 1960 to 2009 by region. Particularly in the past decade or thereabouts, spending by today's middle-income group of countries (which includes Brazil, India, and China – BIC) grew rapidly. By 2009 this group of countries had caught up with the high-income countries as a group in terms of their agricultural R&D spending; both groups of countries spent approximately US $16 billion on public agricultural R&D in 2009 (As a group the BIC countries spent US$10.5 billion (2005 PPP) on public agricultural R&D in 2009, 2.3 times the corresponding amount spent by the United States in that year.). Over this same time period, the 28 countries in today's low-income group (of which 24 are from sub-Saharan Africa) made little headway vis-à-vis the rest of the world. In 2009 they collectively spent US$0.82 billion (2005 PPP) on agricultural R&D, equivalent

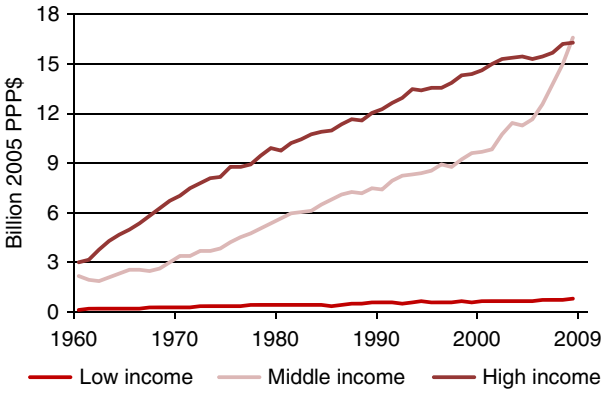

Figure 6 Public agricultural R&D spending by income class, 1960–2009. PPP$, purchasing power parity conversion factor dollar. Eastern European and Former Soviet Union countries are excluded. to just 2.5% of the respective high- or middle-income totals that year.

Figure 7 highlights key elements in the changing structure of global public agricultural R&D worldwide. The share of total R&D done by China, and thus the BIC aggregate, shrank substantially throughout the 1960s, a response to the turmoil of the Great Leap Forward and the subsequent Cultural Revolution (and causing the initial decline in the middle-income totals plotted in Figure 6). As Fan and Pardey (1992) described, during 1960–61, one-third of the Chinese Academy of Agricultural Sciences (CAAS) institutes were moved to rural areas or disbanded and the Academy's total number of staff declined by 70% from 7500 to 620 personnel (CAAS was established in 1957 (Fan and Pardey, 1992, p. 31).). From a

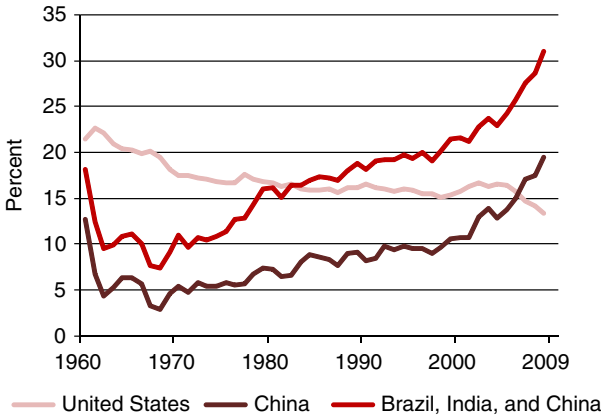

Figure 7 Shifting shares of global public agricultural R&D spending, 1960–2009. Reproduced from Pardey, P.G., Chan-Kang, C., Dehmer, S., 2014b. Global food and agricultural R&D spending, 1960–2009. InSTePP Report. St Paul, MN: University of Minnesota.

50-year low of 3.0% of global agricultural R&D spending in 1968, China's share of the total grew steadily to 10.7% in 2001 and thereafter grew rapidly to 19.5% by 2009. The BIC trend followed a similar path, such that by 2009 these three countries alone accounted for 31.2% of the world total and 60.5% of the low- and middle-income total. The flip side of these developments is a declining share of the world's total both for today's high-income countries as a group and for most of the countries within this group (specifically 20 out of 33 countries) as illustrated by the US share plotted in Figure 7.

These changes in the global structure of public agricultural R&D reflect a shifting pattern of growth in R&D spending among countries and regions of the world. Figure 8 shows the average rate of inflation-adjusted growth in spending by decade since 1960 for five regions of the world. A pronounced and persistent trend is the long-run ratcheting down in the rate of growth of public spending in the high-income countries: from an average rate of 9.1% per year in the 1960s to just 1.0% per year for the decade beginning in 2000.

The generally slower pace of spending growth in Latin America and sub-Saharan Africa compared with the Asia and Pacific region is also evident. All three of these regions saw real agricultural R&D spending growth rebound in the last decade of the data presented here, but the recovery is much more marked in Asia and Pacific than the other two regions. Moreover, the 1980s and 1990s were dismal decades in terms of spending growth in Africa and Latin America and especially so in Africa during the 1990s when overall spending shrank (in real terms). For sub-Saharan Africa and the Latin America and Caribbean regions the recent recovery was not widespread and appears fragile. In sub-Saharan Africa, more than half the increase in spending from 2000 to 2009 came from just two countries (Nigeria and Angola), whereas Brazil accounted for more than half the increased spending in the Latin America and Caribbean region during this same period.

In the early 1960s, the top 10 countries ranked by public agricultural R&D spending accounted for 62% of the world's total spending; by 2007–09, they accounted for 67%. Not only has the spatial concentration in the conduct of public

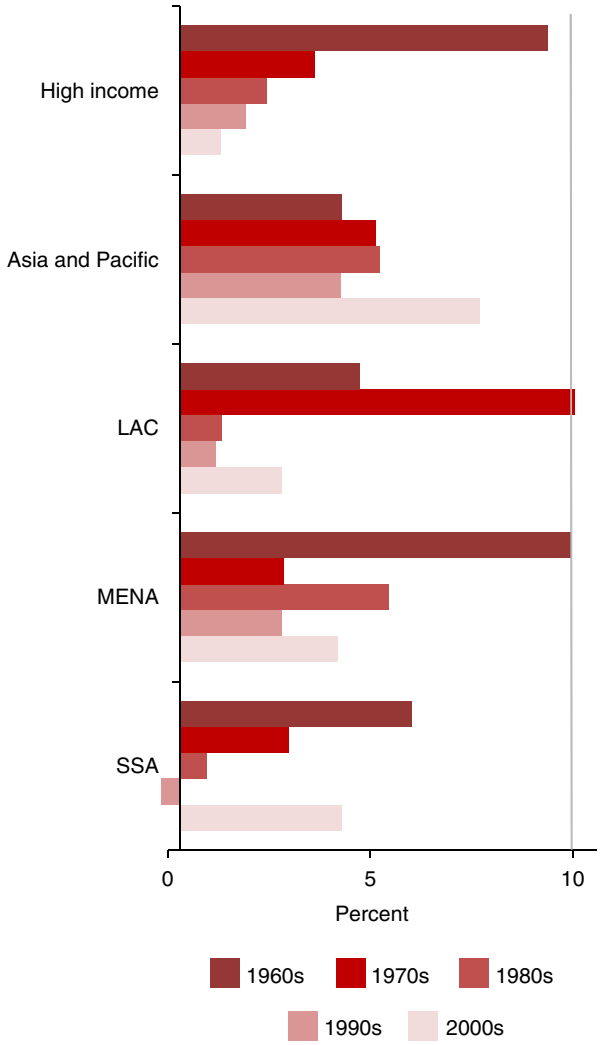

Figure 8 Rates of growth in public agricultural R&D spending by decade, 1960–2009. Eastern European and Former Soviet Union countries are excluded. All growth rates were adjusted for inflation and were calculated using the least-squares method (i.e., as the slope of a regression of logarithms of variables against trend) described in World Bank (2011, p. 409). The 1960s indicates the period covering 1960–1970 and likewise for other decades. Adapted from Pardey, P. G., Chan-Kang, C., Dehmer, S., 2014b. Global food and agricultural R&D spending, 1960–2009. InSTePP Report. St Paul, MN: University of Minnesota.

agricultural R&D become more pronounced over the past half century, but also the ranking of countries in terms of the amounts spent on public agricultural R&D has changed markedly. In the early 1960s, the first-ranked United States spent almost three times more than the second-ranked China (Table 1). By 2007–09, China was spending measurably more than the United States. Germany dropped in the ranking, as did the United Kingdom (5th in 1960 vs. 13th in 2009). By 2007–09, Australia had also dropped out of the top ten (down to 16th). New entrants into the top ten are Brazil (11th in 1960–62 and 5th in 2007–09), Spain (38th to 9th), and South Korea (14th to 10th). India also moved markedly up the

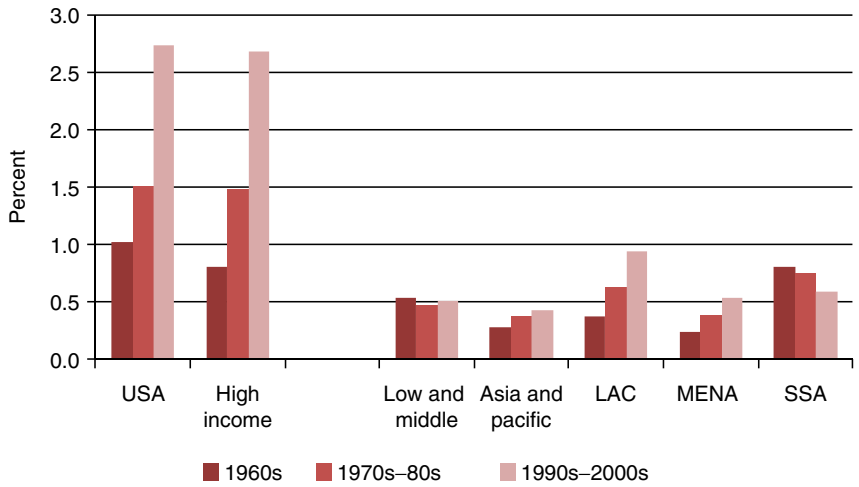

Figure 9 Agricultural research intensities by region, 1960–2009. Agricultural GDP from World Bank (2012) and United Nations (2011). These agricultural research intensity ratios express food and agricultural R&D spending relative to agricultural GDP. Agricultural R&D data details given in Pardey, P.G., Chan-Kang, C., Dehmer, S., 2014b. Global food and agricultural R&D spending, 1960–2009. InSTePP Report. St Paul, MN: University of Minnesota.

ranking from eighth to fourth. This represents a significant change in the geoeconomic order of public agricultural R&D investments, with the historically richer countries ceding ground in more recent years to those with rapidly rising per capita incomes.

Research Intensities

Countries with larger (smaller) agricultural economies are likely to invest more (less) in agricultural R&D simply because of a congruence effect (Pardey *et al.*, 1989). For this reason, normalizing agricultural research expenditures with respect to the size of the agricultural economies they serve gives one indication of the intensity of research spending. The research intensity ratios summarized in Figure 9 are (weighted) averages by decades of the amount of public agricultural R&D spending relative to the corresponding agricultural GDP (ag GDP).

Over the past 50 years, the high-income group has progressed steadily toward an evermore research-intensive mode of agricultural production (Figure 9). Compared with an average of just 56 cents for every UA$100 of agricultural output in 1960, these countries invested an average of US$3.59 per year into public agricultural R&D per hundred dollars of output in 2009. R&D intensity has increased in spite of a slowdown in the rate of growth of agricultural R&D spending, an indication of an even more pronounced slowdown in the rate of growth of agricultural output in these countries. In contrast, the intensity with which the Asia and Pacific region invests in agricultural R&D has grown much more modestly from 0.40% of ag GDP in 1960 to 0.54 in 2009. Although this region has sustained growth in agricultural R&D spending at a

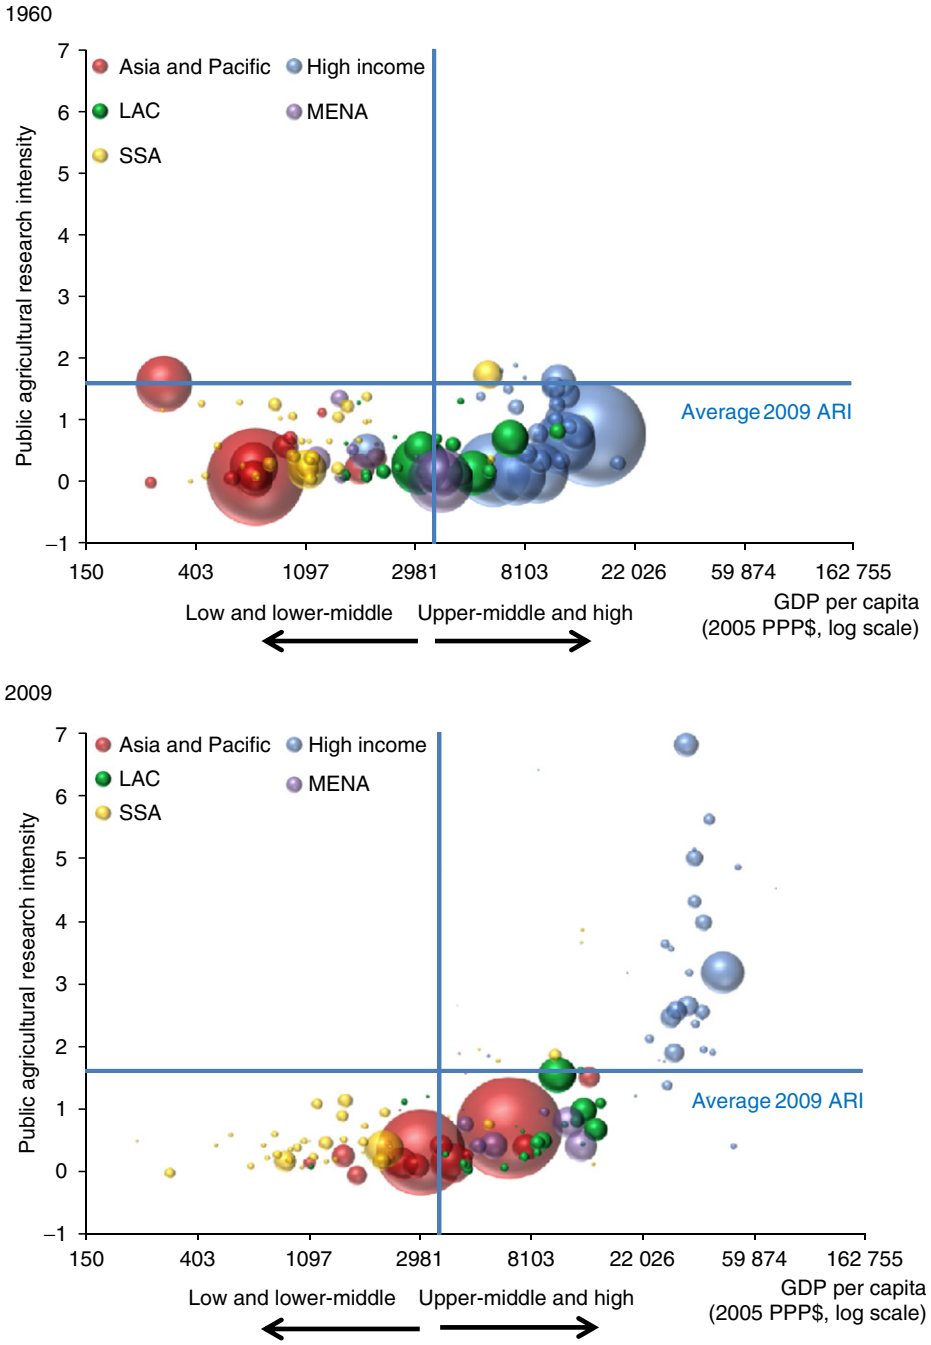

Figure 10 Agricultural research intensities and stage of development, by country 1961 versus 2009. PPP$, purchasing power parity conversion factor dollar. The area of the circle that represents each country is proportional to that country's agricultural GDP in the respective year. Reproduced from Pardey, P.G., Chan-Kang, C., Dehmer, S., 2014b. Global food and agricultural R&D spending, 1960–2009. InSTePP Report. St Paul, MN: University of Minnesota.

comparatively rapid pace – averaging 5.0% per year since 1960 – agricultural output has grown at reasonably rapid rate as well (3.85% per year). Thus, even though the growth in spending on agricultural R&D outpaced the corresponding growth in the value of output, the growth rate differentials were comparatively modest such that the region's research intensity only inched up over time, although increasingly so after the mid-1990s. In sub-Saharan Africa, research intensities have been slipping, especially in the past couple of decades: with 51.2% (22 countries) of the 43 countries in sub-Saharan Africa having lower research intensities in 2009 than what they had in 1980. The same pattern is evident in the low-income countries more generally, with 53.6% of the 28 low-income countries for which relevant data are available similarly losing ground.

Figure 10 offers further insight into the changing world order in terms of agricultural production and the corresponding

investment in public agricultural R&D. In this figure, each bubble represents a country, colored according to its region of production, and the size of the bubble represents that country's share of global agricultural output (ag GDP). In 1960, the high-income countries dominated agricultural production and public agricultural R&D. In the 50 years since then, the higher-income countries have shrunk in relative importance as agricultural producers, and their agricultural intensities have risen. The most striking change though is the increase in relative importance of the middle-income countries – especially China, India, and Brazil – both as agricultural producers and as performers of agricultural R&D. These countries are now poised to play a role in the coming 50 years that was played by today's high-income countries in the past 50 years. At the same time, many of the world's poorest countries continue to lag behind, both in terms of their share in global agricultural production and the relative intensity by which they invest in agricultural R&D.

Stocks of Knowledge and International Research Spillovers

(This section draws heavily on Pardey and Beddow (2013).). Trends in public sector national spending on agricultural R&D may misrepresent the cross-country gaps in scientific knowledge (Stocks of privately held knowledge are also economically important but are not quantified here, partly because of a lack of data.). Science is a cumulative endeavor, with a snowball effect. Innovations beget new ideas and further rounds of innovation or additions to the cumulative stock of knowledge. The mutually beneficial effects of accumulating and exchanging ideas is why lone innovators have largely given way to institutional approaches to research, why scientific disciplines formed professional organizations and spawned journals to capture and carry forward findings, and why scientists seek out other scientists and their ideas at conferences, via the internet and other venues. And so the size of the accumulated stock of knowledge, not merely the amount of investment in current research and innovative activity, gives a more meaningful measure of a country's technological capacity.

The current stock of productive knowledge and the contribution of past research spending to that stock are sensitive to the types of science being done, the institutional structures surrounding the science, and the economic context that affects the use of this stock. Some science spending makes persistent and even perpetual contributions to the changing stock of locally produced knowledge: the same spending in societies ravaged by wars, institutional instability, and outright collapse may have a much more ephemeral effect. Here two types of knowledge stocks are developed. One is a measure of the accumulation of productive knowledge from a country's own R&D (dubbed 'homegrown' knowledge) and the other a measure of the potential stock of knowledge spill-ins from R&D done elsewhere in the world.

Homegrown knowledge

To the public, agricultural science seems to progress through a series of breakthroughs, irrespective of whether it is the invention of tractors, hybrid corn, bioengineered pest or herbicide-resistant crops, or drip irrigation. The occasional genius does make a great leap forward, but the magic of science stems from the slow and steady accretion of new knowledge. Today's scientists stand firmly on the shoulders of those who went before them. Although investments in research give rise to new ideas, knowhow, and innovations in the near term, these innovations draw directly on the efforts of past research. Thus, innovation is a cumulative process. Stocks of productive knowledge, representing an accumulation of the past and present R&D used in agriculture, can thus be viewed as a metric of the state of innovation.

Pardey *et al.* (2014e) developed money measures to quantify the stocks of productive knowledge that resulted from spending on publicly performed agricultural R&D in the United States and around the world. In calculating own-country knowledge stocks, they accounted for the lag between research spending and the production of useful knowledge: expenditures in a given year do not only make immediate or near-term additions to the knowledge stock, but also continue to generate a stream of knowledge over the subsequent half-century. In one of the models applied by Pardey *et al.* (2014e), the productivity benefit of a given R&D investment increases each year for 24 years, then begins to decrease as the knowledge depreciates until it essentially no longer adds to the stock of knowledge by approximately 50 years after the investment. Using the data on country-by-country R&D spending from 1960 to 2009 summarized above (and taken from Pardey *et al.*, 2014b), along with this lag structure (initially developed by Alston *et al.*, 2010b), the global, public pool of productive scientific agricultural knowledge used in agricultural production in 2009 was estimated to be approximately US$18.6 billion (2005 PPP dollars). Approximately one-third of the world's agricultural knowledge stock was generated by three countries, the United States (14.9%), Japan (11.2%), and China (7.1%); nearly half of the world's agricultural knowledge stock was generated by seven countries (the three listed previously, plus Brazil, Russia, the United Kingdom, and Italy).

To aid in interpretation, the world is divided into six groups. First, the 33 high-income countries are separated out regardless of where they are located. The remaining middle- and low-income countries are grouped by region: Asia and Pacific (19 countries), Eastern Europe and the Former Soviet Union (EE&FSU, 28 countries), Latin America and Caribbean (LAC, 24 countries), the Middle East and North Africa (MENA, 7 countries), and sub-Saharan Africa (SSA, 43 countries). The 33 high-income countries account for approximately 56% (an average share of 1.7% per country) of world agricultural knowledge stocks, whereas the sub-Saharan African countries account for approximately 6%, or an average of 0.14% per country. The regional breakdown of world agricultural knowledge stocks is shown in **Figure 11**, where the size of each rectangle represents a region's share of the global stock of agricultural knowledge. Each region is subdivided into its constituent countries, with each country's rectangle scaled accordingly. Of particular note is that although some regions account for a relatively small share of world agricultural knowledge stocks, there are still countries within the regions that play an important role in generating new knowledge. For example, China, Brazil, Russia, South Africa, and Nigeria all account for relatively large shares of the global public stock of productive agricultural knowledge.

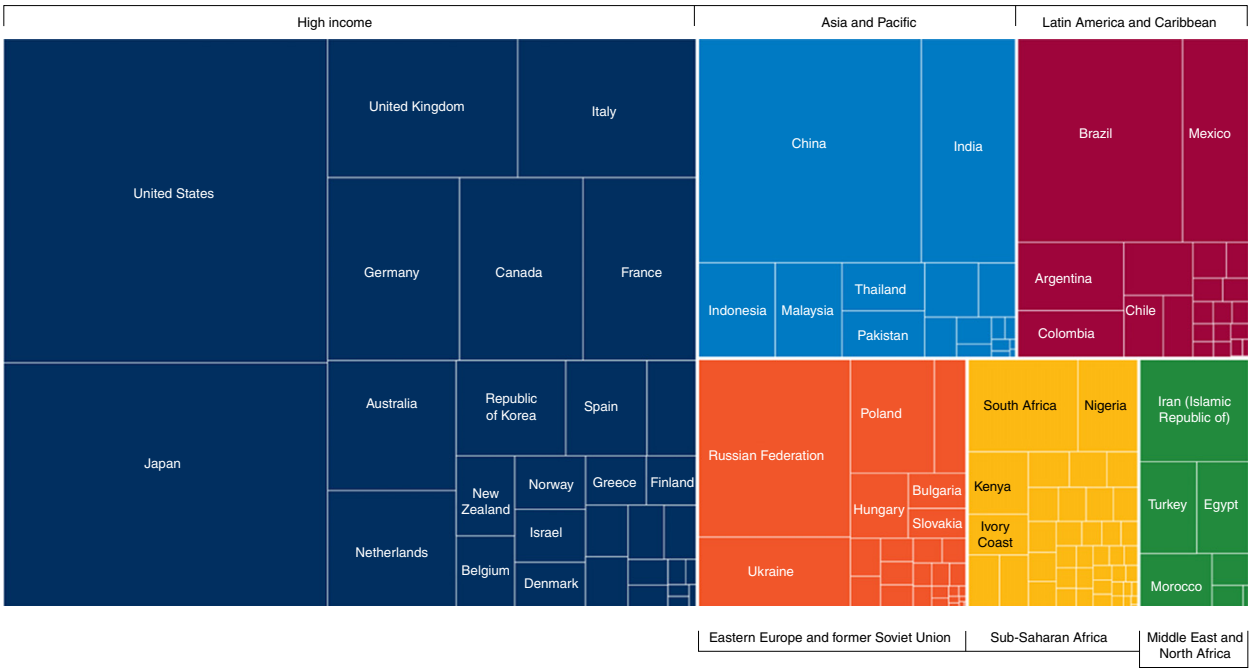

Figure 11 Cumulative homegrown knowledge stocks, by region and country, 2009. Reproduced from Figure 17 in Pardey, P.G., Beddow, J.M., 2013. Agricultural innovation: The United States in a changing global reality. CCGA Report. Chicago, IL: Chicago Council on Global Affairs.

Other peoples' knowledge

Before the modern scientific age, great advances in American agricultural productivity resulted from the efforts of plant prospectors who imported new and improved crop varieties from foreign lands. Walter Burling of Mississippi imported a new cotton variety from Mexico in 1806 that would become the mainstay of the early American cotton industry; Agoston Haraszthy helped to transform the California wine industry by importing several hundred grape varieties from across Europe, North Africa, and the Middle East in the 1860s. In addition to the efforts of private citizens, the USDA sent its scientists to the far corners of the globe in search of better plant varieties (As early as the mid-1850s the federal government employed 'agricultural explorers' to scout the globe for new plant and seed material for shipping back to the United States (Ryerson 1933, p.117). US Navy expeditions and Consular staff were also regularly used to collect new plant material from countries around the world and ship that material back to the United States. Juma (1989) placed these early seed-scouting endeavors in an international context, which is then linked to contemporary interests concerning genetic resources and modern biotechnologies. (See also Olmstead and Rhode (2008).). These efforts were particularly fruitful in introducing varieties of wheat and other crops suitable for the relatively arid and harsh conditions on the Great Plains.

R&D spillovers are still of substantial if not increasing economic importance to US agriculture. For example, foreign entities accounted for 64% of all the plant varietal rights in the United States in 2008 (compared with just 21% in 1984) (Pardey *et al.*, 2014a). By the early 1990s, approximately one-fifth of the total US wheat acreage was sown to varieties with CIMMYT ancestry, and in 1993 virtually all the California spring wheat crop was grown with varieties from CIMMYT or CIMMYT-based ancestors (Pardey *et al.*, 1996). The United States' reliance on wheat varieties from CIMMYT and elsewhere in the world persists (Pardey and Beddow (2013, p. 10) examined the genetic pedigree of the hard-red wheat variety Jagger, released commercially in 1995 as a joint product of the Kansas agricultural experiment station and the USDA's Agricultural Research Service (USDA-ARS). By 2005 this was the most widely planted variety in the United States, occupying 11% (i.e., 5.5 million acres) of the total US wheat area and more than 25% of the area in states such as Kansas and Oklahoma. They found that almost 70% of Jagger's antecedent varieties came from places and breeding efforts outside the United States.).

The reliance on R&D spillovers goes well beyond wheat varieties. A comprehensive study by Alston *et al.* (2010a) of the state-by-state returns to all the state-level investments in agricultural R&D performed in the United States estimated that, on an average, one-third of the economic benefits from research-induced productivity gains in agriculture in each state were attributable to spill-ins from research done in other states or by the federal government. A myopic view of innovation policy would consider only recently and locally performed R&D. A more nuanced approach is to recognize that R&D findings spill across national borders (typically in both directions, in and out of a country) and to be explicit about these spillovers when forming innovation policies, particularly when deciding how much to invest in agricultural R&D and who should pay for it.

Drawing on a concept of 'technological proximity' first used by Jaffe (1989), Pardey *et al.* (2014e) calculated the potential for agricultural knowledge to spill into each country from each other country, averaging the potential based on agroecological similarity and production similarity. For

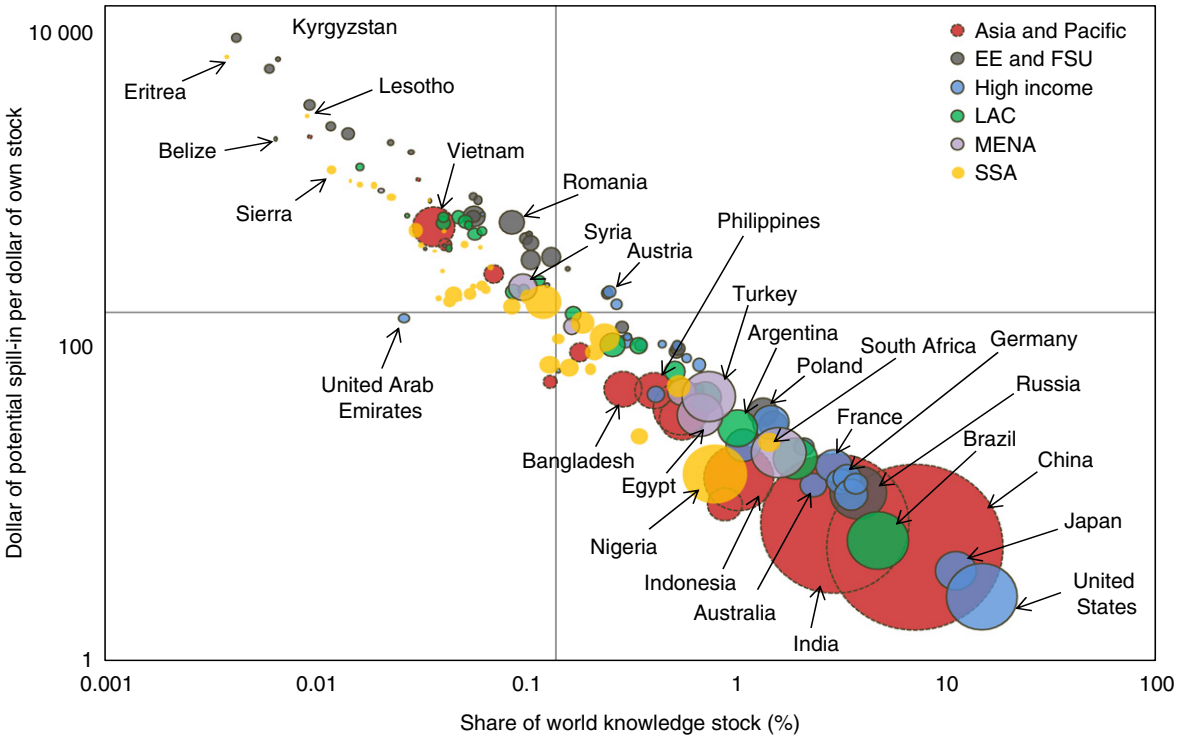

Figure 12 Potential spill-in leverage versus world share of knowledge stock, by country, 2009. The area of the circle that represents each country is proportional to that country's agricultural GDP in 2009. Reproduced from Figure 19 in Pardey, P.G., Beddow, J.M., 2013. Agricultural innovation: The United States in a changing global reality. CCGA Report. Chicago, IL: Chicago Council on Global Affairs.

example, by this measure approximately 49% of US agricultural knowledge could be applicable to Danish agriculture, whereas only approximately 29% of its agricultural knowledge might be applicable to South Africa. For a given country, the total knowledge that could spill in from another country is given by the percentage similarity multiplied by the stock of knowledge in the other country. Summing these values for all countries provides an estimate of the total global stock of knowledge that might be relevant to each country – the amount that could spill-in.

In Figure 12, each country is represented by a circle, and once again the area of which is proportional to the corresponding country's agricultural GDP in 2009. The colors of each circle represent geopolitical groupings of countries. Just five countries (China, India, the United States, Indonesia, and Nigeria) accounted for approximately one-half of the entire world's agricultural output. The horizontal axis of Figure 12 shows each country's share of the world's pool of productive, public agricultural knowledge, whereas the vertical axis shows the ratio of the total amount of relevant knowledge that could spill-in relative to each country's own stock of knowledge. The United States is positioned on the far right of the horizontal axis, with the largest share (14.9%) of the 2009 global public stock of knowledge: Eritrea is on the far left with the smallest share (just 0.004%) (Countries with very small agricultural knowledge stocks or with insufficient data to estimate knowledge stocks are not shown in Figure 12.). Reading of the vertical axis, a ratio of, for example, 1000 indicates that for each dollar a country invests in agricultural R&D, it could potentially tap US$1000 of spill-in knowledge. All countries have positive spill-in ratios – ranging from approximately 2.6 for the United States to 15 for Nigeria and more than 7000 for Eritrea – and therefore all countries can potentially benefit from knowledge generated elsewhere.

There are a few agricultural technologies that can be transplanted from one country to another without modification. Alston and Pardey (1999) broached the idea of diseconomies of economic distance in R&D and its implications for R&D spillovers, and their core idea holds here as well. As a region, by some measure, is more distant (technologically different) from another, the costs of adapting R&D increase. A high spill-in ratio indicates that a large pool of knowledge could potentially be adapted to the local environment, and that much technology could likely be used with little or no modification. Decline in spill-in ratios indicates that relative to the domestic stock, there is less foreign knowledge to tap.

Most of the sub-Saharan African countries have above-average potential spill-in ratios, and all but Nigeria and South Africa could potentially access at least 25 times their locally produced agricultural knowledge by adapting and adopting technologies produced in other countries. Thus, these areas show great potential for tapping foreign knowledge. Countries with relatively low spill-in ratios, such as the United States, Japan, China, and Brazil, could also potentially tap large knowledge stocks, but the relative cost of importing versus producing knowledge locally might be higher on average (Pardey *et al.*, 2014e). Thus, it is not clear that countries with both low potential spill-in ratios and large domestic

agricultural R&D enterprises would be as successful in adapting foreign knowledge as would countries with high spill-in ratios and small domestic R&D systems. Nonetheless, all countries have sizable spill-in potentials that should be integral to domestic decisions about the orientation and operational details of their own R&D efforts.

Internationally Oriented Agricultural Research and Development

(This section draws heavily on Pardey and Beddow (2013). See also Alston *et al.* (2006).). Progress in agriculture has always been an inherently international affair. The global diffusion of agriculturally significant plants and animals, their accompanying pests and diseases, and the tools and techniques used in production agriculture has been a pivotal part of the history of agricultural innovation. An important event in this history was the 'Colombian Exchange' that was initiated when Columbus first made contact with native Americans in the 'New World' (Crosby, 1987; Diamond, 1999; Olmstead and Rhode, 2008). Most of the commercial agriculture in the United States today is based on crop and livestock species introduced from Eurasia (e.g., wheat, barley, rice, soybeans, grapes, apples, citrus, cattle, sheep, hogs, and chickens), although with significant involvement of American species (e.g., corn, peppers, potatoes, tobacco, tomatoes, and turkeys).

More formal forms of international collaboration in the development and diffusion of agricultural innovations, designed to enhance the international spillovers of technologies and techniques, crystallized in the first half of the twentieth century. Baum (1986, pp. 5–6) and Culver and Hyde (2000) attributed the original idea of providing rich-country research assistance to developing-country agriculture to Henry A. Wallace, who founded the Pioneer Hi-Bred International Company in 1926 and served as US Secretary of Agriculture from 1933 to 1939 and as Vice President of the United States in the Roosevelt administration from 1940 to 1944 (Perkins (1997, p. 106) and Wright (2012, p. 1720) also pointed to the pivotal role played by Wallace in seeding the Green Revolution.).

Efforts to develop formal centers of international collaboration began in the 1940s and continued through the 1960s with the founding of four international research centers that would become the core of the Consultative Group on International Agricultural Research (CGIAR, or CG for short) system. By 1970 the budgets of the four founding centers totaled US$15 million. With the creation of the CGIAR in 1971, the system began expanding over the next two decades (**Figure 13**). The total number of centers increased, as did the funding per center, with funding reaching US$305 million in 1990 (US$422 million in 2005 dollars). After an abrupt cessation of growth in funding during the 1990s, funding began increasing again after 2000, reaching US$643 million (US$580 million in 2005 dollars) by 2010.

Over time, as agricultural productivity increased and donor priorities began to change, the allocation of funding among centers also changed. Throughout the 1970s and 1980s overall CG spending in real terms grew at a substantially faster rate (9.7% per year) than the spending by the four founding centers (5.6% per year) (Through 1971, all funding went to the four founding CG centers. During the 1970s, real funding for the four founding centers grew 9.9% per year. During the 1980s, however, the rate of growth of real funding slowed to an average of 2.5% per year and then declined for the following 15 years, before beginning to grow again in 2005 at an average annual rate of 6.5 per year from 2005 to 2010.) At the same time there was a broadening of the scope of the system beyond the main staple food crops, which was the focus of the founding centers, to include commodities, such as potatoes, livestock, sorghum, millet, bananas, and plantains. Funding was also targeted to agricultural development issues, such as food policy and the management of NARS. Mirroring domestic agricultural research policy developments in the rich countries that mainly fund the CG, during the 1990s the scope of the system broadened further to encompass forestry, fishery, water, and other issues. As a consequence, CG activities now

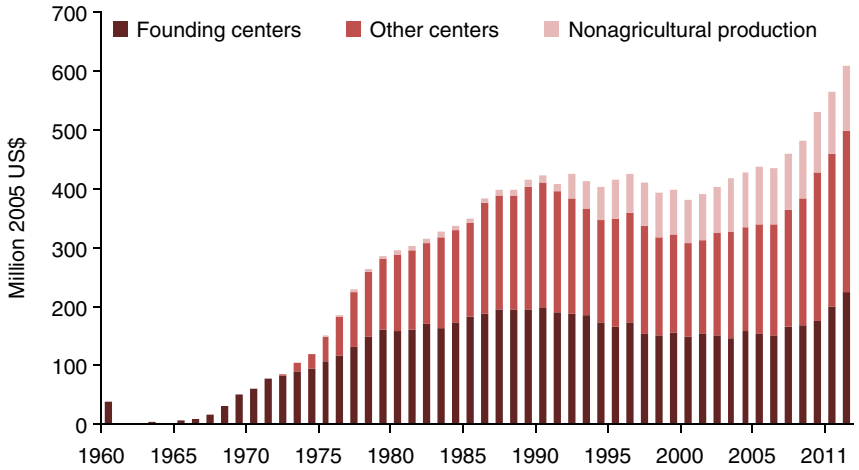

Figure 13 Real expenditures of the CGIAR, 1960–2011. Data in US dollars deflated to 2005 prices with implicit GDP deflator from the Bureau of Economic Analysis (2012). Reproduced from Figure B6 in Pardey, P.G., Beddow, J.M., 2013. Agricultural innovation: The United States in a changing global reality. CCGA Report. Chicago, IL: Chicago Council on Global Affairs.

give less weight to directly enhancing the productivity of the main staple food crops, relative to other activities (This is in line with similar trends in rich countries that provide the majority of funding for the CG. For example, in 1976 approximately 65% of the research conducted by the state agricultural experiment stations in the United States was targeted to increasing, or at least maintaining, farm productivity. By 2009, only 56% of the research had this orientation, as research into human nutrition, the environment, energy, and other areas of policy and social concern gained ground (Pardey *et al.*, 2014c).).

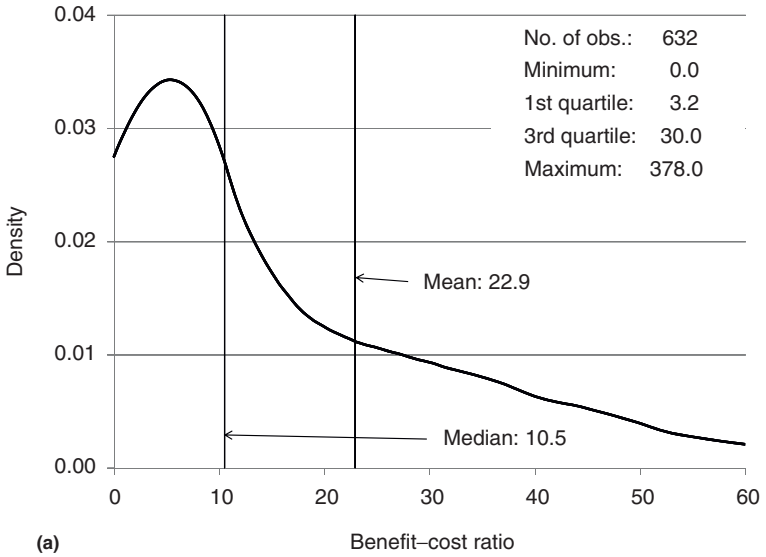
The long-run shift in CG priorities has been dramatic. Of the total increase in funding for the CG since 1990 (US$158 million in inflation-adjusted 2005 dollars) only 1.3% of that increased funding went to the four founding centers (or 36.0% if other centers that do research on specific agricultural commodities are also included, such as the International Potato Center, the International Center for Agricultural Research in the Semi-Arid Tropics, the International Network for the Improvement of Banana and Plantain (now merged with Bioversity International), and the International Livestock Research Institute. The overwhelming majority of the additional funds (64%) were directed to issues other than productivity improvements in crop and livestock production. In 1990 the four founding centers constituted 47.2% (almost one-half) of the total CG funding. By 2010 their share had fallen to 34.7% (just more than one-third) (Unfortunately, the CG has not maintained a set of science indicator statistics that enable funding trends to be meaningfully parsed into commodity-specific or other research program areas. Here the shift in center-specific funding is being used to illustrate the shift away from 'research' on staple food crops. The extent to which CG funds are used for research vs. other purposes (e.g., outreach- or extension-type activities, training, agricultural development efforts, or even administrative overhead) is also difficult to determine, impossibly so it seems for meaningfully examining long-term trends in these attributes.).

The size and scope of CGIAR activities vis-à-vis investments globally in food and agricultural research has also changed markedly. Although the CG substantially accelerated the spread of new varieties of wheat, rice, and other technologies (commonly called the Green Revolution), it now receives only a small, and of late, declining fraction of the global agricultural research investment dollars. In 2009, it represented just 1.6% of the US$34.12 billion spent on public sector agricultural research worldwide – or 3.1% of the research spending of the low- and middle-income countries combined (**Figure 5**) (In 1990, the CG constituted 5.3% of public agricultural R&D spending by the low- and middle-income countries.).

Perhaps even more dramatic is the shift in the size of the CG relative to particular rich and middle-income countries. In 1970, public spending on agricultural research in the United States was 31 times more than that of the CGIAR (US$1883 million against US$60.7 million for the CG in 2005 dollars), falling to just 8.5 times larger than the CG in 2009. In contrast, Brazil, India, and China as a group spent 19.6 times more than the CG in 1970, increasing slightly to 19.8 times more than the CG in 2009 (If private sector research is also factored in, the United States was 52.7 times larger than the CG in 1970 and 20.3 times larger in 2009.).

The Returns to Investments in Agricultural Research and Development

(This section draws heavily on Hurley *et al.* (2014a,b).). What is the economic worth of these substantial investments in food and agricultural R&D worldwide? It takes time – often many years – for research to generate tangible technologies and commercially useful ideas, and it takes time after that to fully realize the resulting economic benefits, not least as the uptake of new agricultural technologies often takes a decade or more. To estimate the economic worth of agricultural R&D, economists have developed summary measures that take account of the timing of the flows of costs and benefits. One such measure is the benefit–cost ratio (BCR): the (discounted) present value of the benefits divided by the (discounted) present value of the costs. This measure requires the choice of a suitable discount rate to be used to convert the streams into present values. Another popular summary statistic is the internal rate of return (IRR): the discount rate that equates the present value of the benefits and the present value of costs. An investment is deemed profitable if its benefit–cost ratio is greater than one (i.e., the present value of the benefits exceeds the present value of costs) or if the computed IRR is greater than the required (market) rate of return. Both of these conventional measures have been applied to evaluating agricultural research investments, but some issues have been raised about the interpretation of the results.



Conventional Measures of the Returns to Research and Development

Zvi Griliches published the first formal economic estimate of the rate of return to agricultural R&D more than half a century ago (Heckman (2006) wrote that "early empirical work on the social rate of return to research activity (Griliches, 1958), and on the role of economic incentives in determining the distribution of benefits from new technologies (Griliches, 1957), laid the foundations for scientific study of these topics." Schultz (1953) gave the earliest known economic estimate of the overall benefits attributable to public agricultural research in the United States but did not report a formal benefit–cost ratio or an internal rate of return.). Since then many economists have published a large number of estimates. Hurley *et al.* (2014a,b) reported a compilation of 2242 evaluation estimates from 372 separate studies published between 1958 and 2011 (Prior compilations include Alston *et al.* (2000), Evenson (2001), and Fuglie and Heisey (2007). After correcting some errors (and dropping several studies that reported only producer or consumer surplus estimates) in the compilation developed for Alston *et al.* (2000), the authors added 81 new studies published during the period 1999–2011 that reported 392 additional IRRs or BCRs.). This includes a total of 2049 IRR estimates and 632 BCR estimates, with 76 studies (20% of the total) reporting both BCRs and IRRs for the same program of research. Nearly half of the studies (and 42% of the estimates) were published in the 1990s. Around 38% of the studies were published in refereed journals. The rest were published in books, graduate dissertations, conference papers, and a good deal of gray

literature, including reports published by various international and national agencies.

The preponderance (99%) of the published evaluation evidence pertains to research carried out by public agencies (including either state or national government or international organizations along with universities). Approximately one-third of the reported evaluations for publicly performed R&D pertain to research done jointly, say by a government agency in collaboration with a university, whereas 28% of the estimates pertain to research that involved universities. Approximately 7% cover joint public and private research, whereas just 0.9% involves privately performed R&D. The CGIAR centers carried out the research encompassed by 12% of the evaluation estimates (and approximately 18% of the studies).

One-third of the evaluation estimates refer to research performed by federal or state agencies (including land-grant universities) in the United States. Research conducted by institutions from the Asia-Pacific, Latin America-Caribbean, and sub-Saharan Africa regions account for 14%, 13%, and 12% of the evaluation estimates, respectively. Almost 6% of the

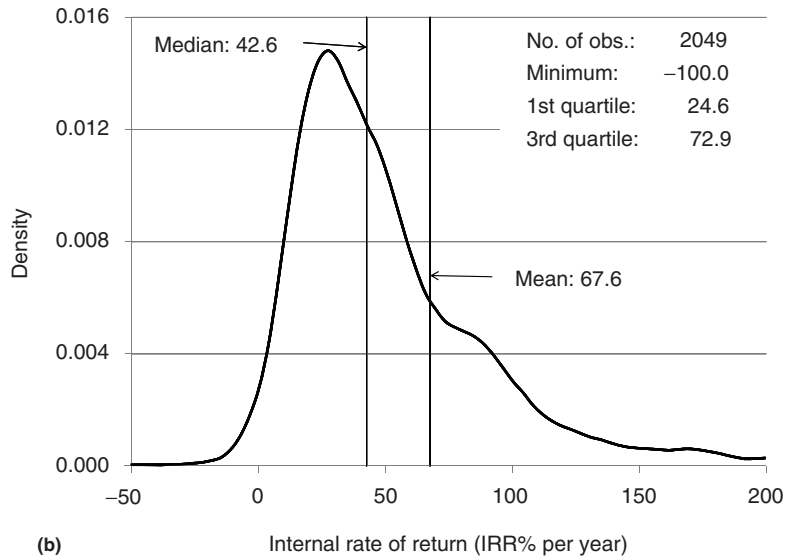


Figure 14 Distribution of reported benefit–cost ratios and internal rates of return. (a) Benefit–cost ratios and (b) internal rates of return. (a) Plot represents a Kernel density estimate (kernel = epan2, bandwidth = 4.9) fitted across 632 BCR estimates. For presentation purposes the plotted observations were truncated at 60. (b) Plot represents a Kernel density estimate (kernel = epanechnikov, bandwidth = 7.0) fitted across 2049 IRR estimates. For presentation purposes the plotted observations were truncated at 200. American Journal of Agricultural Economics, with permission from Oxford University Press.

estimates pertain to multinational research (i.e., research spanning multiple countries), with nearly 40% of these estimates dealing with research carried out by the CGIAR.

More than half of the estimates refer to joint research and extension activities. Around 38% of the estimates refer to broadly defined research investments that included both basic and applied research. Only a limited number of the estimates (close to 1%) refer exclusively to either basic research or extension. A little more than one-quarter of the estimates refer to research related to cereal crops, with maize and wheat research getting the most attention followed by rice. Assessments of aggregate investment in research for 'All agriculture' make up another fifth of the estimates, followed by livestock research, which accounts for approximately 10% of the estimates. This compilation also includes a small number of assessments of natural resources research, forestry research, and joint crop and livestock research.

Griliches' seminal 1958 study reported both the IRR and the BCR, although Griliches expressed a preference for the BCR. This preference appears to have eluded many subsequent researchers: 93% of the compiled studies report IRRs, with only one in three studies reporting BCRs and only one in five reporting both. Figure 14 (a) and (b) show the distribution of BCRs and IRRs, respectively, and other common descriptive statistics. The average BCR is 22.9 (i.e., in present value terms, on an average agricultural R&D yields US$22.9 of benefit for every dollar invested in R&D), although the distribution is right skewed and so the median (10.5) provides a more robust measure of the centrality of the estimates. The average IRR is 67.6% per year. Again the distribution is right skewed, with a median of 42.6% per year. The minimum is a dismal −100% per year, whereas the maximum is an incredible 5645% per year. Seventy-five percent of these IRRs exceed 24.6% per year, whereas a quarter exceed 72.9% per year.

Table 2 provides summary measures that characterize the distribution of the reported IRRs stratified by the type, commodity focus, and geographical orientation of the R&D. It includes measures of the central tendency of these distributions (specifically their mean and median values, the latter perhaps a more informative measure given the highly skewed

nature of the distributions) and indications of the dispersion of the estimates (specifically minimum and maximum values and the 5th and 95th percentiles). The substantial variation in the methodological details used to estimate the reported IRRs summarized in Table 2 cautions against overinterpreting the apparent differences in the returns to different types, commodities, or location of performance of research.

Modified Internal Rates of Return to Research

Using IRRs to summarize R&D benefit and cost streams is problematic. Alston *et al.* (2011) criticized the IRR as a measure of investment returns, pointing to a conceptual flaw in the method, the implausibly high values that are typically obtained as a result, and the questionable implications of these values – a dollar invested at an annual rate of return of 50% per year would be worth in excess of US$11 million after 35 years and US$600 million after 50 years – and they suggested using a BCR or a modified internal rate of return (MIRR) instead. As subsequently elaborated by Hurley *et al.* (2014a,b), the implausibly high estimated values are the result of two key assumptions used in the IRR calculation. First, the calculation assumes that the beneficiaries (i.e., farmers and consumers) can reinvest their benefits at the same rate of return (i.e., the computed IRR). Second, the cost of the investment over time is discounted at the same rate (i.e., the computed IRR). These two assumptions are generally questionable and are empirically problematic when the computed IRR is very large, as is typically true for investments in agricultural R&D. In computing the MIRR the analyst chooses values for the rates of discount for research costs and rates of return to reinvested research benefits. If more reasonable assumptions are made about rates of discount for research costs and rates of return to reinvested research benefits, the computed MIRR will be much smaller than the conventional IRR, and typically much more plausible, as demonstrated by Alston *et al.* (2011) and Andersen and Song (2013).

Hurley *et al.* (2014a,b) developed a methodology for using information reported in previous studies to recalibrate a subset (270) of the previous IRR estimates using the MIRR. With this recalibration, the mean MIRR is 13.6% per year, which is 82% lower than the mean corresponding IRR of 67.9% per year. The interquartile range of the MIRRs is less varied, just 15% of the corresponding range for the IRRs, and with a much reduced median of 9.8% per year. The minimum MIRR is −2.0% per year, whereas the maximum MIRR is 107.0% per year, well below the corresponding IRR estimate of 1736% per year.

Conclusion

Agricultural R&D is a crucial determinant of agricultural productivity and production and therefore food prices and poverty. In this article, the authors present new evidence on investments in public agricultural R&D worldwide as an indicator of the prospects for agricultural productivity growth over the coming decades. The agricultural R&D world is changing, and in ways that will definitely affect future global patterns of poverty, hunger, and other outcomes. The overall picture is one in which the middle-income countries are growing in relative importance as producers of agricultural innovations through public investments in R&D and have consequently better prospects as producers of agricultural products, although the important role of privately performed R&D gives a substantial innovative edge to the higher income countries where most of this R&D takes place.

The economic impact of this research has been much studied, and the overwhelming conclusion drawn from this evidence is that the returns to agricultural R&D have been large. However, some have questioned the evidence, and there are reasons to be skeptical about some aspects of it (e.g., Alston and Pardey, 2001). The reinvestment rate assumptions implicit in the calculations used to derive internal rates of return (IRRs) – the statistic of choice used to summarize the returns associated with a given cost of research – are part of the estimation problem, which can be addressed by using a MIRR to summarize the same research benefit–cost streams. The recalibrated MIRR estimates of the rates of return to public agricultural R&D are more modest but still substantial compared with the opportunity cost of the funds used to finance the research. This still suggests that society has persistently underinvested in public agricultural R&D, notwithstanding the distorted view of the evidence created by reliance on the IRR to represent the returns to this investment that has characterized the literature for the past 50 years. If this underinvestment continues and the supply of important agricultural staples fails to keep pace with the growth in aggregate demand, increasing food prices will further stress the world's most vulnerable populations.

Glossary

Denitrification The process of microbially facilitated reduction of nitrate into nitrogen (N_2) gas and other nitrogen oxides.
Ecosystem service Benefits to humankind from a multitude of resources and processes that are supplied by natural ecosystems.
Gray water Water output of a food production (or other) system that is degraded in comparison to the fresh (blue and green) water inputs.
Hydromorphology Hydrological, habitat, and structural processes and features of rivers, lakes, and coastal waterbodies.
Nitrate vulnerable zone A term used in Europe for areas of land that drain into nitrate-polluted waters, or waters which could become polluted by nitrates.
Pollution swapping The outcome of mitigation practices is positive for one natural resource but negative for another.

Agricultural Catchment Water Quality

Surface Water Quality Problems

Freshwater is a scarce and valuable resource (FAO, 2011). Conservation and equitable distribution of freshwater is therefore critical to sustaining ecosystem services and global food production (Rockstrom *et al.*, 2009). Agriculture uses 70% of global freshwater and so optimizing water use through advanced irrigation, farm, and food processing systems is paramount to meeting the globally increasing demands for food, particularly in the face of a changing climate. With the quantity of freshwater available, all human activities affect the quality of freshwater resources, and degradation of water quality in turn increases the scarcity of freshwater (Peters and Meybeck, 2000). Impaired water quality also limits ecosystem services, and human welfare and livelihood (Ongley, 1996; FAO, 2011). Poor water quality can cause loss of aquatic and riparian biodiversity, ecosystem stability and recreation value, poor human health (e.g., due to unsanitary drinking water and toxins from harmful algal blooms), physical disruption to water supply systems, shellfish contamination, fish kills, and reduced aquaculture production (Carpenter *et al.*, 1998; Schindler, 2006; Withers and Haygarth, 2007; Kay *et al.*, 2009).

Eutrophication and sedimentation are two common processes leading to water quality degradation. Eutrophication is an increased rate of organic matter supply to a waterbody, which can lead to excessive algal growth, species composition changes, taste and odor problems, changes in aesthetics, and oxygen depletion when algal blooms decompose. Both natural and human-induced processes lead to hypoxic (reduced oxygen) and anoxic (no oxygen) conditions in waterbodies (Rabalais *et al.*, 2010). The main cause of eutrophication in waterbodies is the oversupply of nutrients. Nitrogen supply commonly limits eutrophication in marine waters and phosphorus supply commonly limits eutrophication in freshwaters. However, colimitation or the reverse scenarios also occur (Boesch *et al.*, 2001). Sedimentation is the deposition of suspended soil and other particulate matter on river, lake, and estuary beds. Accelerated levels of suspended and deposited sediment can disturb the habitats for macroinvertebrates, aquatic flora, and fish spawning (Donohue and Molinos, 2009). Other significant causes of water quality degradation include accumulation of pesticides, other persistent organic pollutants and heavy metals, and changes in salinity, pH, thermal regime, and hydromorphology (i.e., waterbody structure, habitat, and hydrological processes) (Tognetti and Lawrence, 2002).

 doi:10.1016/B978-0-444-52512-3.00077-2

Impacts of Agriculture

Detrimental water quality impacts in rivers, lakes, groundwater, and coastal waters have been attributed to impacts from agriculture, forestry, urban, and industrial land use (Carpenter *et al.*, 1998). During the 1980s and 1990s, there was considerable success in reducing nutrient inputs to waterbodies from human wastewater and industrial discharge, such that agricultural inputs have become a higher total proportion of overall inputs in many cases (Schindler, 2006; Kronvang *et al.*, 2008). This is the case in Lough Neagh in Northern Ireland, where the dominant source of phosphorus gradually switched from urban discharge to agricultural inputs after controls on urban discharge were introduced in the 1980s (Foy *et al.*, 2003). Globally, agricultural 'gray' water (polluted freshwater) volumes are estimated to be large (53%) compared with industrial (26%) and domestic (20%) users of 'blue' (surface and groundwater) and 'green' (consumed rainwater) water (Mekonnen and Hoekstra, 2011). The current nitrogen use is estimated to far exceed the planet's boundaries of sustainability and phosphorus transfer from land to water has almost reached the planet's functionally sustainable threshold (Rockstrom *et al.*, 2009).

Pressures (i.e., stressors on the environment) on waterbodies in agricultural catchments include enhanced losses of nutrients and eroded soil, changes to the natural hydrologic regime, increased losses of agrochemicals, pathogens and organic compounds, and acidification (Carpenter *et al.*, 1998; Blann *et al.*, 2009; Quinton *et al.*, 2010; Carpenter *et al.*, 2011; Foley *et al.*, 2011).

In Europe, pressures from agriculture are significant in 40% of rivers and coastal waters, and in one-third of lakes and transitional waters (EEA, 2012). Brown tides in China have been linked to turbidity, dissolved organic carbon, and metals exports, which have been partly linked to intensification of agriculture (Gobler *et al.*, 2011; Qiu, 2012; Zhang *et al.*, 2012a). In the Aral Sea basin in Central Asia, overextraction of water for irrigation caused a 90% decline in the lake volume between 1960 and 2006 and an increase in lake salinity, leading to large-scale abandonment of fishing industries, land desertification, and to poor ecosystem and human health (Micklin, 2007). Other examples of where impaired water quality has been linked to agricultural land use include the Baltic Sea in Europe (Gustafsson *et al.*, 2012), Chesapeake Bay in the United States (Simpson, 2010), and the Great Barrier Reef in Australia (Waterhouse *et al.*, 2010).

Technical Options for Water Quality Mitigation

A range of stewardship approaches, including engineering solutions that treat the symptoms, and management practices that minimizes the pressures, is needed to mitigate against anthropogenic pressures on the planet's resources (Steffen *et al.*, 2011). In agriculture, practices aimed at mitigating environmental degradation are interchangeably referred to as 'mitigation measures', 'stewardship approaches' and 'best, recommended, conservation or sustainable' management practices and can be classified as cultural or structural measures. Cultural measures (e.g., fertilizer application rate, form, placement, and timing) are land management practices that modify the spatial and temporal availability of nutrients and pollutants for mobilization and transport to waterways. Structural measures (e.g., slurry storages, riparian fences, and vegetation) are those that modify the pathway of nutrients, pollutants, and water to a receiving waterbody. A range of structural and cultural mitigation measures can be applied at different stages of the link between land management and water quality impact. These stages can be conceptualized as a transfer continuum for materials that are mobilized from sources via pathways of transport and later delivered to a waterbody where they may cause an ecological impact (Haygarth *et al.*, 2005). **Figure 1** highlights the key components of the nutrient transfer continuum for nutrients. Many mitigation measures have benefits for both the off-farm environment and the farm system itself by sustaining the soil, animal, landscape, and water resource. For example, increasing output from similar or lower nutrient use, reducing soil compaction and erosion and enhancing farm water quality have both on- and off-farm benefits (Ridley, 2005; Gourley *et al.*, 2007; Zeckoski *et al.*, 2007; Simpson *et al.*, 2011; Soane *et al.*, 2012). Mitigation measures that target nutrient, agrochemical, sediment and pathogen losses, and greenhouse gas emissions at plot, field, and farm scales have been identified for a range of agricultural industries and climates (Ongley, 1996; United Nations Environment Program, 1998; Sharpley *et al.*, 2000; Campbell *et al.*, 2004; McKergow *et al.*, 2008; Kay *et al.*, 2009; Merriman *et al.*, 2009; Monaghan, 2009; Sharpley *et al.*, 2010; Newell Price *et al.*, 2011). The effectiveness of each mitigation measure described in this section is often highly site-specific and needs to be targeted to each agricultural landscape to avoid neutral or negative impacts on the environment.

Mitigating Sources

Structural and cultural practices that optimize the magnitude, timing, and spatial distribution of nutrient, contaminant, and sediment sources can mitigate losses to catchment waterways and in many cases also increase farm profitability, particularly when efficiency of the farming system is increased (Monaghan *et al.*, 2008). Source management is often more practical and feasible than water management in rain-fed farming systems. In the Republic of Ireland, for example, more than half of the mandatory agricultural mitigation measures are focused on managing point and diffuse nutrient sources (Statutory Instrument 610, 2010).

A EU-wide upper limit on the rate of organic nitrogen in manures that can be applied through spreading or animal grazing has been set at 170 kg ha^{-1} (with some exceptions allowed) in an effort to minimize nitrogen (and phosphorus) losses to receiving waterbodies. Practices that maintain agricultural production while decreasing the use of fertilizers are also encouraged. For example, to reduce inorganic fertilizer requirements, manures and slurries that are produced when stock are housed in farm yards can be captured, stored, and later redistributed to fields. However, investing in the infrastructure and spreading equipment and developing the skills required to utilize manures as fertilizers is an on-going

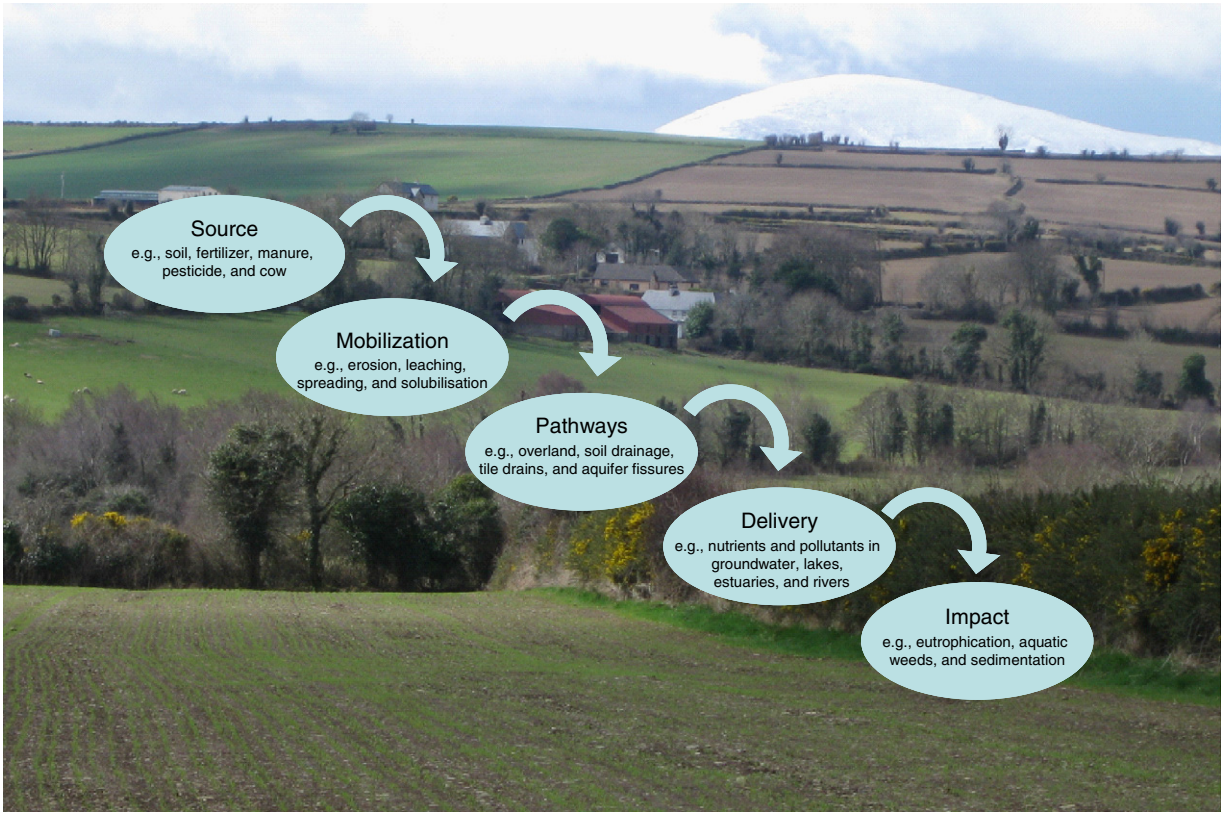

Figure 1 Good agricultural practices and targeted implementation of mitigation practices can reduce the mobilization and delivery, via flow pathways, of nutrient, agrochemical, and sediment sources so that detrimental impacts in receiving waterbodies are minimized. Imagery courtesy of Teagasc, Ireland.

challenge for livestock farmers (Kleinman *et al.*, 2012). To maximize the value of nutrient use, and minimize losses to the environment, manure and fertilizer should be applied at appropriate rates, timings, and locations to match crop requirement, maximize crop uptake, and minimize leaching of nitrate and volatilization of ammonium compounds (Di and Cameron, 2002; Lalor *et al.*, 2011). Soil management practices that minimize nitrogen leaching include use of cover crops, minimal plowing of pasture (particularly in early autumn), improved stock management, and precision farming (Di and Cameron, 2002). Certain fertilizer formulations can also be used to reduce nitrogen losses from cropping systems to the environment (Chen *et al.*, 2008).

Comprehensive reviews of measures suitable for mitigating phosphorus sources in a range of farming systems are provided by Kronvang *et al.* (2005), Nash and Halliwell (1999), and Sharpley *et al.* (2000). Availability of phosphorus sources for loss to waterways can be minimized by matching fertilizer and manure application rates to match crop needs, and not applying fertilizers to soils that have stores of plant-available phosphorus higher than crop requirements (Richards, 2006). Timing phosphorus applications to fields in ways that avoid forecast heavy rain, choosing appropriate fertilizer formulations, and placing fertilizer away from the main water flow pathway (e.g., subsurface placement of phosphorus fertilizers and manures) can reduce the risk of losses in runoff and drainage (Hodgkin and Hamilton, 1993; Nash *et al.*, 2004). Avoiding stocking or fertilizing areas within fields that seasonally saturate can reduce losses because the wettest parts of the landscape contribute a disproportionately large amount of runoff and nutrients to downstream waterbodies (Melland *et al.*, 2008; Sharpley *et al.*, 2011).

A range of soil amendments (e.g., gypsum, lime, bauxite mining residues, siderite, refuse ash, dredged river sediments, alum hydrosolids, ferrous sulfate, and cement kiln dust) increase the soil's capacity to retain phosphorus against leaching, mostly due to their iron, aluminum, or calcium content (Summers *et al.*, 1996; Callahan *et al.*, 2002; Murphy and Sims, 2012), however, these amendments are not widely applied. Soil management practices that maintain a threshold level of groundcover and minimize compaction will minimize erosion and runoff of nutrients. Practices include rotating stock between fields and optimizing stock densities to efficiently utilize but not overgraze pasture, controlling farm machinery traffic, and minimizing tillage operations (McCaskill *et al.*, 2003; Agouridis *et al.*, 2005; Deasy *et al.*, 2010; Godwin, 2012).

Mitigating Pathways

A key mitigation strategy for reducing nutrient and contaminant loads in surface and subsurface pathways is to reduce the interaction between water, as a transporting

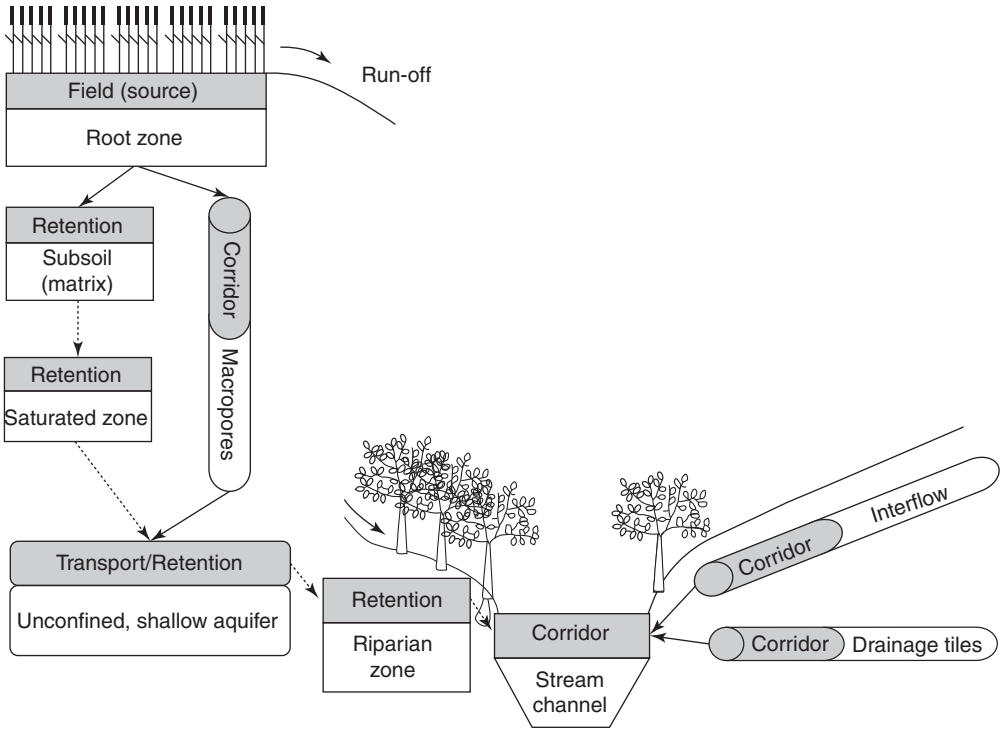

Figure 2 Pathways of nitrate movement from fields to a stream. Nitrate can be transported in water rapidly to streams through natural pipes (corridors) such as tile drains and old root channels and can also flow more slowly through soil and groundwater aquifers and be taken up by plants or biologically transformed into other nitrogen forms (retention). The retention processes attenuate, or deplete, the amount of nitrate reaching the stream. Reprinted from Haag, D., Kaupenjohann, M., 2001. Landscape fate of nitrate fluxes and emissions in Central Europe: A critical review of concepts, data, and models for transport and retention. Agriculture, Ecosystems and Environment 86, 1–21.

medium, and the source of the nutrient or contaminant. Interaction can be reduced by reducing the volume or energy of water flow, by redirecting the pathway of water flow, or by removing the source from the water flow pathway, either in space or time. For example, nitrate nitrogen that drains from the root zone via old root channels or subsurface drains (i.e., high energy flow) may rapidly reach a stream without attenuation (**Figure 2**). In contrast, nitrate that flows through lower energy water pathways such as soil drainage and riparian zones may be retained and naturally attenuated (depleted) by plant uptake or by biological transformation (e.g., via denitrification) into gaseous nitrogen forms (see Section Pollution Swapping). For phosphorus, the optimum spatial arrangement of mitigation practices on a farm can be guided by identifying areas that transfer disproportionately high amounts of phosphorus. These areas usually have both a high source of phosphorus and a high potential for surface runoff and are termed critical source areas (Sharpley *et al.*, 2011). A range of phosphorus and nitrogen loss risk assessment indices and models have been developed to identify the critical source areas in farmed landscapes (Buczko and Kuchenbuch, 2007, 2010) and are the subject of continuing research (e.g., Shore *et al.*, 2013).

The volume of soil drainage can be decreased through increasing plant water uptake by planting deep-rooted perennial forage crops instead of shallow-rooted annual crops (White *et al.*, 2003). Efficient irrigation management can also decrease volumes of surface runoff and subsurface drainage (Wilcock *et al.*, 2011). Slowing water in drainage ditches using vegetation and low-grade weirs allows attenuation of nitrogen and phosphorus (Ensign *et al.*, 2006; Kröger *et al.*, 2011). Retention of runoff water in constructed wetlands can also enable denitrification of nitrate and uptake and sediment adsorption of phosphorus, sedimentation, degradation, and decay of pathogenic bacteria (Scholz *et al.*, 2010; Wilcock *et al.*, 2012) and pesticides (Moore *et al.*, 2007; Gregoire *et al.*, 2009). Sediment traps and flow diversion terraces in fields facilitate deposition of sediments entrained in field runoff (Yang *et al.*, 2009; Ockenden *et al.*, 2012). Vegetated riparian buffers have some potential to mitigate inputs of nitrogen, phosphorus, sediment, and fecal inputs (Lovell and Sullivan, 2006; Collins *et al.*, 2007; Kay *et al.*, 2009). Buffers are most effective for reducing sediment and sediment-associated nutrients in cases where surface runoff is slowed allowing for enhanced deposition of sediment. Where infiltration is enhanced, some attenuation of dissolved nutrients and contaminants also occurs.

Separation of clean and dirty water by using appropriate guttering and drainage in farm yards reduces the potential for nutrients and sediment to become mobilized, and diverting runoff from farm lanes can prevent nutrients directly entering streams (Wilcock *et al.*, 2007).

A range of technologies have the potential to remove nutrients from water. Phosphorus is adsorbed and precipitated by aluminum, iron, or calcium compounds in natural, industrial byproduct, or artificial media such as iron oxide,

limestone, steel slag, melter slag, and bauxite mine red mud residue (Buda *et al.*, 2012; Klimeski *et al.*, 2012). Nitrate is removed by denitrification using permeable carbon reactive media (Fenton, 2008), and concentrations of suspended solids, chemical oxygen demand, and total nitrogen are decreased through physical filtration, as well as by absorption and biological uptake in aerobic woodchip filters (Ruane *et al.*, 2011).

Mitigating Direct Delivery

Limiting direct contact between nutrients and other contaminants and a waterbody itself provides a direct means for mitigating losses. Fecal contamination of waterways and erosion from trampled stream banks can be reduced if stock are excluded or discouraged from entering a waterbody. Partial or total stock exclusion can be achieved by riparian vegetation, fencing, providing bridges for crossing, and providing alternative shade and water sources and by managing grazing rotations (Agouridis *et al.*, 2005; Collins *et al.*, 2007; Kay *et al.*, 2008). Minimum distances to watercourses are routinely included in fertilizer spreading and pesticide spraying codes of practices.

Mitigating Impacts

In some cases, the impact of eutrophication can be mitigated through engineering, chemical treatment, and hydromorphological modification; however, these approaches are often prohibitively expensive and the mitigation effect is often temporary. The Mondego estuary in Portugal provides an example of where reducing the water residence time and redirecting inflows and associated nutrient loads to enter a deeper section led to improved water quality status according to some biological and physicochemical indicators (Lillebo *et al.*, 2007). Elsewhere, recovery of eutrophic lakes, dams, and estuaries has been accelerated by (usually costly) technologies that remove nutrients including chemical amendment (with lime, ferric aluminum sulfate, and other phosphorus binding products), aeration, dredging, harvesting macrophytes, flushing to reduce water residence times, and manipulation of the food web (Humphries and Robinson, 1995; Schindler, 2006; Gafsi *et al.*, 2009). Phosphorus binding and filtering products have also had some success situated near to and within streams (McDowell and Nash, 2012) and manipulating light and temperature through shading can also minimize eutrophic impacts (Bowes *et al.*, 2012).

Pollution Swapping

Pollution swapping is a term used to describe the outcome of mitigation practices that is positive for one natural resource but negative for another. Stevens and Quinton (2009) reviewed the pollution swapping potential of mitigation methods (cover crops, residue management, no-tillage, riparian buffer zones, contour grass strips, and constructed wetlands) in combinable cropping enterprises. They found potential for pollution swapping via increased greenhouse gas emission after retaining crop residues, establishing riparian buffer strips, or constructing wetlands for sediment loss control, via increased nutrient leaching due to crop residue retention, and via runoff of nutrients, particularly soluble phosphorus and dissolved organic carbon due to the reduced efficacy of riparian buffers and constructed wetlands over time. In another case, vegetated riparian buffers reduced eroded sediment inputs to streams, however, less suspended sediment was then available to adsorb phosphorus from the water so concentrations of the most algal-available phosphorus form increased as a result (McKergow *et al.*, 2006). The suitability of zero tillage cropping varies depending on the soil type and climate and can lead to increased greenhouse gas emissions from wet heavy clay soils and increased runoff of dissolved phosphorus from accumulation of phosphorus near the soil surface in some circumstances (Soane *et al.*, 2012). **Table 1** summarizes some of the advantages and disadvantages of zero-till cropping in Europe. Mitigation measures, therefore, need to be targeted to the desired outcome and to specific soil types and agricultural systems in order to optimize both mitigation and production.

Governance, Costs, and Benefits of Water Quality Mitigation

Costs and Benefits

The costs of implementation, the technical feasibility, and the adoptability of practices can all constrain the effectiveness of farm practice change measures related to water quality (Buckley *et al.*, 2012). In the European Union, the Water Framework Directive requires the member states to calculate the cost-effectiveness of policies that are implemented. Derogations from Water Framework Directive objectives are allowable where it can be demonstrated that achieving such objectives would involve disproportionate costs (Kallis and Butler, 2001). Calculating cost-effectiveness requires both a measure of the costs of implementation and a measure of the effect of the policies on water quality (Balana *et al.*, 2011). Owing to the complexities of estimating the costs of a suite of mitigation measures in a diverse agricultural socioeconomic and physical landscape, costs are often modeled for a range of actual or theoretical farming systems scenarios (Fezzi *et al.*, 2008). Similarly, physical effects of measures are difficult to measure with certainty (see Section Monitoring and Evaluation of Mitigation Effectiveness) and are therefore frequently modeled (e.g., as marginal abatement costs) rather than measured directly (Fezzi *et al.*, 2010). Importantly, the impacts of mitigation measures vary between agricultural landscapes and over time, so cost-effectiveness needs to be measured or modeled for each landscape and time frame of interest.

Cost-effectiveness of mitigation measures has been modeled for a range of farming systems and landscapes. Source mitigation approaches such as altering the way nutrients are managed at farm level are often cost neutral or cost beneficial (Ribaudo *et al.*, 2001; Zhang *et al.*, 2012b). For example, reducing the risk of nutrient transfer to the aquatic environment through a more efficient use of chemical fertilizer potentially has a double dividend effect of increased returns to agricultural production (Barnes *et al.*, 2009; Huhtanen *et al.*, 2011; Buckley and Carney, 2013). In the United Kingdom, optimal

Table 1 Advantages and disadvantages of plowing and no-till farming in Europe, although not universally relevant to all regions

Moldboard plowing		*No-till*	
Advantages	*Disadvantages*	*Advantages*	*Disadvantages*
Appropriate loosening of topsoil before seedbed preparation	Pan formation below the depth of plowing (from passage of plow sole and tractor wheels)	Lack of compaction below plow furrow	Crop establishment problems during very wet or very dry spells
Complete burial of weeds, crop residues, lime, other amendments and manure	Excessive looseness to depth of plowing	High work rates and area capability	Weed control problems
Inversion allows structural development of lower layers in the topsoil	Exposure of bare topsoil to wind and water erosion	Increased bearing capacity and trafficability	Cost of herbicides, herbicide resistance
Exposes soil compacted at harvest to loosening by weather	High susceptibility to recompaction of topsoil	Reduced erosion, runoff and loss of particulate P	Risks of increased N_2O emissions and increased dissolved reactive P leaching
Increased mixing of nutrients throughout profile	Buried weed seeds brought to the surface	Opportunity to increase area of autumn-sown crops	Reduced reliability of crop yields, especially in wet seasons
Promotes surface drainage leading to warmer, drier seedbed in spring	Reduced trafficability under wet conditions	Stones not brought to the surface	Unsuited to poorly structured sandy soils
Reduced risk of crop diseases	Low work rate and high costs	Drilling phased to take advantage of favorable weather conditions	Unsuited to poorly drained soils
Reliable agronomically in widely differing seasons	Increased CO_2 emissions (fuel and oxidation of SOC)	Increased area capability	Risk of topsoil compaction
Suitable for preparing a seedbed after grass	Greater oxidation of organic matter near surface	Reduced overall costs (fuel and machinery)	Problems with residual plow pans
	Disruption of macrofauna (earthworms, predatory insects)		Increased slug damage
			Unsuited for incorporation of solid animal manures

cost-effective measures for reducing nitrate leaching were modeled as reducing stocking rates and annual grazing duration, and substitution of cropping area to grassland (Fezzi *et al.*, 2008; Cardenas *et al.*, 2011). For mitigation of phosphorus in runoff, measures that targeted pathways of loss were modeled as more effective than source management, and amongst the most cost-effective of the pathways measures were sediment traps and riparian buffers (£4–8 (US$6.5–13, conversion rate as of 15 December 2013) per kg phosphorus conserved) (Haygarth *et al.*, 2009). In contrast, to mitigate phosphorus exports from dairy farms in Australia and New Zealand, source management strategies were calculated to be more cost-effective (NZ$0–200 (US$0–165) per kg phosphorus conserved) than using amendments or edge-of-field methods to capture phosphorus (McDowell and Nash, 2012). Similarly, in Ireland, source management to deplete surplus P in the soil was identified as the most cost-effective long-term strategy for water quality improvement in the Lough Melvin catchment (Schulte *et al.*, 2009).

At the river basin scale, Roberts *et al.* (2012) identified, through modeling, that costs to implement agricultural, forestry and river management changes sufficient to meet aspired nutrient pollution reduction targets for the impaired Gippsland Lakes in eastern Victoria, Australia (AU$1 billion (US$0.9 billion) over 25 years) exceeded the available environmental budget. They proposed that discussion around environmentally acceptable mitigation measures should center on cost-effective, politically realistic, and technically feasible options. Optimizing the spatial arrangement of measures also increases the cost-effectiveness (Qi and Altinakar, 2011; Doole *et al.*, 2013). Cost–benefit analysis, which places monetary values on both costs and the effects of measures, identified that farmyard improvement and establishing vegetative buffers in critical source areas was effective in reducing phosphorus loss but only became cost beneficial 15 years after implementation in one study (Rao *et al.*, 2012).

Water Quality Governance

Rogers and Hall in Hoekstra (2006) define water governance as "the range of political, social, economic and administrative systems that are in place to develop and manage water resources, and the delivery of water services, at different levels of society." Recognition of the hydrological connection between upland and lowland parts of catchments has resulted in watersheds (river basin boundaries) frequently being used as administrative boundaries for water management (Ferrier and Jenkins, 2010). For example, natural resource management planning within river basin boundaries is an integral

component of the Water Framework Directive legislated in Europe since 2000 (Official Journal of the European Community, 2000). Many countries also share river basin resources (e.g., Mekong, Nile, and Danube), which leads to a high dependency on water quantity and quality governance upstream (Hoekstra, 2006; Murphy and Glasgow, 2009).

A range of policy instruments and mechanisms are used in water quality management, specifically to link upstream and downstream water users (Tognetti and Lawrence, 2002). These mechanisms include regulatory instruments (Statutory Instrument 610, 2010; Daroub *et al.*, 2011), economic instruments, and mechanisms to increase market access (Dabrowski *et al.*, 2009; BenDor and Riggsbee, 2011); modifying organizational structures (Ridley, 2005); education, awareness-building, and participatory approaches (Ridley, 2005; Ulén and Kalisky, 2005; Bergfur *et al.*, 2012; Doody *et al.*, 2012). **Table 2** shows an example of the suite of agricultural policies imposed since 1985 to reduce nutrient transfers to waterbodies in Denmark (Kronvang *et al.*, 2008). The choice of mechanism(s) can be usefully informed by an account of the likely ratio and type of public and private benefits that will occur as an outcome of structural or cultural practice change (Pannell, 2008). Adaptive planning and implementation approaches and fit-for-purpose governance structures are the key features of what is known as integrated catchment management (Hammer *et al.*, 2011; Pahl-Wostl *et al.*, 2012). The potential beneficiaries of mitigation practices such as land and water user groups and commodity boards are being increasingly involved in catchment and water governance (Millenium Ecosystems Assessment, 2005). Payments for ecosystem services (FAO, 2004), and farmer-led movements such as Landcare in Australia (Youl *et al.*, 2006), exemplify recognition of the multiple benefits (i.e., environmental, food and fiber, employment, and community) provided by farmers as stewards of the land.

Monitoring and Evaluation of Mitigation Effectiveness

Accounting for Investments in Environmental Management

Despite the large number of plot to farm-scale studies on technical mitigation options for water quality, there is a relative paucity of evidence that these measures improve water quality at larger spatial scales and also over long temporal scales. Evidence for the effects of mitigation measures on water quality is required to account for public and private funds spent implementing those measures, to inform the scientific foundation for the implementation of a measure, and to help inform expectations about the potential in time and space for those measures to achieve anticipated water quality targets. In some cases expectations of natural resource condition improvement are not realized despite expenditure on research, development, extension, incentives/subsidies, and penalties. In many cases insufficient monitoring exists to demonstrate whether change has occurred. Since 2002, a nationwide evaluation of more than 50 years of conservation practices and 38 catchment assessment studies (the Conservation Effects Assessment Project) was initiated in the United States to account for US$6 billion in expenditure on these practices (Weltz *et al.*, 2005). In Australia, AU$1.4 billion (US$1.25 billion) was spent for more than 7 years to remediate salinity of soils and groundwater; however, there was little evidence of mitigation as a result of this expenditure (Pannell and Roberts, 2010). In the European Union, monitoring the impact that policies affecting agricultural practice have on water quality is mandatory in zones declared as Nitrate Vulnerable Zones (e.g., in England, France, Sweden, Czech Republic, and the Walloon region of Belgium) and is a prerequisite for stocking rates above a European Union cap on manure-nitrogen loading to be permitted. Some member states have identified the whole country as a Nitrate Vulnerable Zone (e.g., The Republic of Ireland, Austria, Luxembourg, Germany, and Denmark) and have accordingly established national and agriculture-specific programs to monitor the impacts of farm practice regulations on water quality (Fraters *et al.*, 2011).

Water Quality Targets and Standards

To measure the effectiveness of mitigation measures, the target condition relating to the water resource needs to be defined. Targets may be defined as chemical load, concentration and exposure, degree of sedimentation, biological quality, hydromorphology, or a combination of indicators (Ongley, 1996). In the United States, total maximum daily loads are used as targets and are defined as the maximum amount of a pollutant that a waterbody can receive and still meet water quality standards. Legislation requires that total maximum daily loads are set for impaired waters; however, implementation of measures to achieve load reductions is largely voluntary or incentivized (Helmers *et al.*, 2007). The European Union Water Framework Directive (Official Journal of the European Community, 2000) set a target for all waterbodies to attain at least 'good' water quality status by 2015 (with 6-year review cycles if the first target could not be met). To monitor progress toward this target, an intercalibration process was conducted (e.g., McGarrigle and Lucey, 2009) so that the water quality status can be compared across the wide range of bioregions and waterbody types across Europe and to account for shared bioregions between jurisdictions. Individual member states have subsequently set their own chemical, biological, and hydromorphological water quality standards. For example, in The Republic of Ireland standards for drinking water and standards designed to protect ecological status have been legislated, with ecological status being constrained by the most limiting of a range of chemical, biological, and hydromorphological indicators (Bowman, 2009). The Australian and New Zealand guidelines for fresh and marine waters require threshold (or 'trigger value') chemical concentrations and biophysical status to be established based on conditions in reference waterbody types (Anon, 2000; McDowell *et al.*, 2013). The choice of indicator of system quality or change can influence assessments of whether mitigation measures have been successful or otherwise. For example, Lillebo *et al.* (2007) found that estuary quality either did not change, improved, or worsened in response to mitigation measures depending on the quality status indicator used in the assessment. Some indicators may not be able to pick up changes due to specific mitigation measures. For example, if loads of nutrients from diffuse sources of episodic overland flow are reduced by

Table 2 Agri-environmental policies implemented in Denmark since 1985 to reduce nitrogen loss from agriculture

Danish policy actions	*Policy measures imposed*
1985: NPo Action Plan to reduce N- and P-pollution	• Minimum 6 months slurry storage capacity • Ban on slurry spreading between harvest and 15 October on soil destined for spring cropping • Maximum stock density equivalent to 2 LU ha^{-1}. (1 livestock unit = 1 LU corresponds to one large dairy cow) • Various measures to reduce runoff from silage clamps and manure heaps • A floating barrier (natural crust or artificial cover) mandatory on slurry tanks
1987: The First Action Plan for the Aquatic Environment (AP-I), aiming to halve N-losses and reduce P-losses by 80%	• Minimum 9 months slurry storage capacity • Ban on slurry spreading from harvest to 1 November on soil destined for spring crops • Mandatory fertilizer and crop rotation plans • Minimum proportion of area to be planted with winter crops • Mandatory incorporation of manure within 12 h of spreading
1991: Action Plan for a Sustainable Agriculture, aiming to reduce N-loses from agricultural fields by 100×10^6 kg N	• Ban on slurry spreading from harvest until 1 February, except on grass and winter rape • Obligatory fertilizer budgets • Maximum limits on the plant-available N applied to different crops, equal to the economic optimum. The economic optimum is calculated annually, taking into account the mineral N in the soil (from a comprehensive soil sampling system) • Statutory norms for the proportion of manure N assumed to be plant-available (pig slurry: 60%, cattle slurry: 55%, deep litter: 25%, other types: 50%)
1998: The Second Action Plan for the Aquatic Environment (AP-II)	• Subsidies to establish 16 000 ha wetlands, designed to reduce nitrate leaching through denitrification and reduced demand for fertilizer • Subsidies to enable reduced nutrient inputs to up to 88 000 ha of areas designated as being specially sensitive with regard to the environment • An expectation that animal feeding practice would be improved to reduce N excretion • A reduction of the stock density maximum to 1.7 LU ha^{-1} • Subsidies to encourage the conversion of 170 000 ha to organic agriculture • The statutory norms for the proportion of manure N assumed to be plant available were increased from 1999 (pig slurry: 65%, cattle slurry: 60%, deep litter: 35%, other types: 55%) • Maximum limits on the application of plant-available N to crops reduced to 10% below the economic optimum • Mandatory 6% of the area with cereals, legumes, and oil crops to be planted with catch crops • Subsidies to encourage afforestation on up to 20 000 ha
2000: AP-II Midterm Evaluation and Enforcement	• Increased economic incentives to establish wetlands • The N assumed to be retained by catch crops must be included in the fertilizer plans • Further tightening of the statutory norms for the proportion of assumed plant-available N in manure. From 2001; pig slurry: 70%, cattle slurry: 65%, deep litter: 40%, other types: 60%; from 2002 pig slurry: 75%, cattle slurry: 70%, deep litter: 45%, other types: 65% • Reduced fertilization norms to grassland and restrictions on additional N-application to bread wheat
2001: Ammonia Action Plan	• Subsidies to encourage good manure handling in animal housing and improved housing design • Mandatory covering of all dung heaps • Ban on slurry application by broadcast spreader • Slurry spread on bare soil must be incorporated within 6 h • Ban on the treatment of straw with ammonia to improve its quality as an animal feed • Options for planning authorities to restrict agricultural expansion near sensitive ecosystems
2004: The Third Action Plan for the Aquatic Environment (AP-III). AP-III is very closely related to the EU-water Framework Directive and the EU Habitat Directive. N-leaching must be reduced by further 13% by 2015	• Further tightening of the request for catch crops

reducing agricultural soil's phosphorus levels, but instream biological quality responds mainly to low-flow nutrient concentrations, then the benefits of the overland flow mitigation measures may not be reflected by biological indicators.

Monitoring Methods

Many of the mitigation measures implemented on farms have been recommended to or by policy makers a result of process studies that relate action to response for individual or small groups of measures (Kronvang *et al.*, 2005; Carton *et al.*, 2008; McDowell *et al.*, 2009). Effectiveness of implementation of measures can also be informed by scenario analysis and modeling of the complex interactions of land management with environmental variables (Silgram *et al.*, 2008; Oenema *et al.*, 2009; Vigiak *et al.*, 2011; van Grinsven *et al.*, 2012). A growing number of studies have also directly measured the impacts of mitigation measures at the catchment scale.

A water catchment, often also referred to as a watershed, is the area of land from which rainfall eventually drains into a surface waterbody. Although surface water catchments are defined by topography and are separated by watersheds, or catchment divides, groundwater zones of contribution to surface waters do not always follow the same topographic boundary. Water catchments provide discrete biophysical spatial units that account for all the anthropogenic and natural chemical, biological, and physical processes that influence the mobilization, transfer, attenuation, and delivery of materials from their sources to receiving surface waterbodies. Headwater catchments that supply water to perennial streams have a significant influence on downstream water volumes and quality despite often being a large distance away (Alexander *et al.*, 2007). An understanding of the degree to which land use and management in these headwater catchments influences inherent hydrological and biogeochemical cycling is therefore important in terms of managing lake, groundwater, and coastal water quality.

Medium-sized headwater catchments, or meso-catchments (also referred to as microbasins (Yates and Bailey, 2006) or small watersheds (Meals *et al.*, 2010)), are commonly 1–100 km^2 and incorporate first- to third-order streams. Measuring the effects of agricultural mitigation practices on water quality in meso-catchments offers advantages over smaller and larger scales in that the size can minimize inputs from non-agricultural pressures, can enable adequate stakeholder involvement in implementing and monitoring agricultural practices, and the integrated and 'net' impacts of attenuating and mobilizing processes and farm types and practices are accounted for (Iital *et al.*, 2008; Fealy *et al.*, 2010). Larger catchments usually include other significant influences such as forestry, industrial, and municipal land use. Also, as the size and scale of the catchment increases, the effects on water quality of individual mitigation practices become more difficult to discern (Kiersch, 2002, **Table 3**).

Approaches for measuring water quality impacts of agricultural mitigation practices in meso-catchments range from measuring water quality over a time series, such as before and after a land management change (e.g., Jaynes *et al.*, 2004), or over a spatial series such as in paired catchments with and without agricultural practice change (e.g., Schilling and Spooner, 2006) or over a gradient of practices or catchment types, and by cause and effect studies that measure sources, pathways, and impacts of practices (e.g., Wall *et al.*, 2011, **Figure 3**).

Table 3 Measurability of land use effects by basin size

Impact type	*Basin size (km^2)*						
	0.1	*1*	*10*	*10^2*	*10^3*	*10^4*	*10^5*
Average flow	x	x	x	x	–	–	–
Peak flow	x	x	x	x	–	–	–
Baseflow	x	x	x	x	–	–	–
Groundwater recharge	x	x	x	x	–	–	–

A dose–response relationship is also sometimes used to describe the increasing impacts on water quality, where the agricultural pressure increases. The European Environment Agency uses the Drivers-Pressure-State-Impact-Response (DPSIR) framework to assess change in the state (S) of natural resources due to changes in specific drivers (D) and pressures (P) that can have an impact (I) and are the focus of policy responses (R) (EEA, 2012). These conceptualizations highlight the biophysical links in space and time between agricultural pressures and water quality in receiving waterbodies. Nutrients, for example, can be transferred from both point and diffuse sources. Point sources include discharges from intermittent or persistent discrete sources (such as a farmyard) to a water flow pathway or waterbody. Diffuse transfers are derived from nonpoint sources, which are spatially widespread, such as nutrients in soil. The connectivity of these sources with receptor waterbodies depends on the activity of, and attenuation potential along, the water flow pathway to the receptor. For example, overland flow transport of soil and nutrients tends to occur episodically during storms and from parts of a catchment that are prone to generate runoff (e.g., saturated areas and hard surfaces).

Effects of agricultural practice on water quality are challenging to measure at the meso-catchment scales because of (1) the resource constraints associated with establishing sufficient monitoring infrastructure and collecting land management information (Cherry *et al.*, 2008), (2) the uncertainty in cause–effect relationships due to the complexity of hydrological, climatic, biogeochemical, and anthropogenic processes occurring in time and space, and because (3) long time scales are normally needed to identify trends in data due to variation in responses through time and due to time lags between implementation of mitigation measures and responses in water

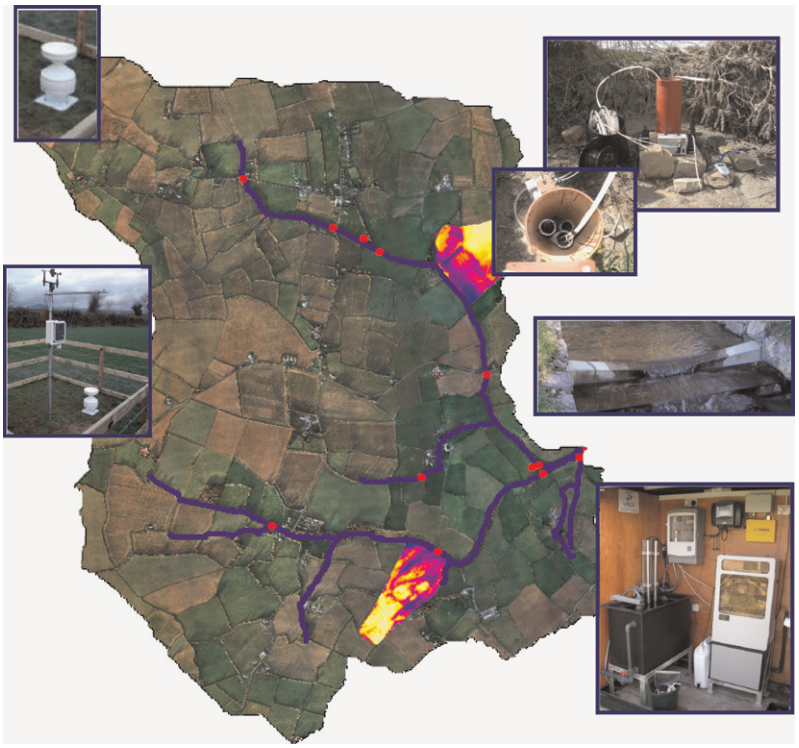

Figure 3 A meso-catchment study of the effects of agricultural nutrient management policies on water quality in Ireland (Wall *et al.*, 2011) includes measurements of subhourly stream discharge and water quality at the catchment outlet, monthly water quality at upstream locations, meteorological parameters, geophysical characteristics and groundwater dynamics and quality in two representative hillslopes, field by field soil nutrient levels, and surveys of farm nutrient management practice and financial data. quality (Spooner *et al.*, 1987; Meals *et al.*, 2010). These challenges are discussed in the Sections Resource constraints, Uncertainty in cause–effect relationships, and Time lags between implementation of mitigation measures and responses.

Resource constraints

Owing to the sometimes 100-fold variation in phosphorus concentrations between baseflow and stormflow in streams, and the likelihood that phosphorus measures are aimed specifically to mitigate surface sources of phosphorus, sufficient sampling intensity of stormflow phosphorus concentrations is required to accurately measure flow-weighted concentrations and loads (Jordan and Cassidy, 2011). Stormflow samples are costly to collect and analyze on a continuous and highly spatially distributed basis. The cost of sampling one site every 7 h for 1 year and analyzing for nutrients was estimated at EUR5000 (US$6900) once-off for equipment and EUR 30 000 (US$41 200) for sampling at 2012 Euro values (Melland *et al.*, 2012). Technologies such as continuous bankside analysis provide opportunities for continuous analysis that importantly capture high flows but are still costly (EUR50 000 (US $68 700) once-off for equipment and EUR30 000 (US $41 200) for sampling) and are often impractical to deploy at multiple locations (Jordan *et al.*, 2007). Passive sampling may offer a compromise between increasing the spatial coverage of sampling and collecting continuous (integrated) nutrient concentrations over storm and baseflows, but the technology is still at the research and development stage (Jordan *et al.*, 2013).

Uncertainty in cause–effect relationships

Effects of measures are difficult to dissociate from potentially overriding/swamping attenuation effects such as groundwater denitrification and stream nutrient uptake and from counteracting effects such as increased intensification of agricultural production (Sutton *et al.*, 2009). The effect of mitigation needs to be large, compared with background processes, so that impacts can be measured and measures can be effectual (Tomer and Locke, 2011). Further to these factors, rates of implementation of mitigation measures are often difficult to control, particularly when there is reliance on voluntary adoption (Yates *et al.*, 2007). Uncertainty in measurement can affect estimates of cost-effectiveness and equity of cost sharing of mitigation (Khadam and Kaluarachchi, 2006). Gren and Destouni (2012) suggest that calculation and presentation of a range of estimates of nutrient loads based on different models is likely to reduce barriers to implementation of measures by identifying commonality in model outcomes (such as consistent attribution of nutrient source or apportionment of mitigation costs) and thus reducing arguments about model outcome uncertainty.

Time lags between implementation of mitigation measures and responses

The time between when a land management activity occurs, and when either a positive or negative response in water quality occurs depends on the type of pollutant and the potential for that pollutant to be mobilized or attenuated along the path it travels to reach a waterbody. Lag times for water

quality improvement in groundwater and groundwater-fed waterbodies after nitrate mitigation can be as long as decades (Fenton *et al.*, 2011), particularly where travel rates through aquifers are slow and there is little opportunity for denitrification (e.g., oxic chalk aquifers in Denmark (Collins and McGonigle, 2008; Fenton *et al.*, 2011; Windolf *et al.*, 2012)). To identify trends in acid-sensitive lake chemistry, 10 years of sulfate chemistry records were predicted to be sufficient for trend analysis but no trends in nitrate were detectable over this time frame due to the biological processes of nitrogen transformations (Skjelkvale *et al.*, 2005). For phosphorus and sediment movement via surface flow pathways, chemical fixation of phosphorus to soil particles and retention and remobilization of particulate and soluble phosphorus forms throughout landscape and channel beds can cause years to pass before water quality improvements from phosphorus mitigation practices occur (Walling, 1999; McDowell *et al.*, 2003; Stutter *et al.*, 2007; Schulte *et al.*, 2010).

Contaminant flow times can impact not only the timing of the response, but also the degree of response. Generally, the longer the contact time between a contaminant and its surrounding flow path media (in this case soils or geological strata), the longer the time available for attenuating reactions (such as sedimentation, denitrification, or phosphorus adsorption) or mobilizing reactions (such as phosphorus desorption and nitrification) to occur (Barrow and Shaw, 1975; Haag and Kaupenjohann, 2001). Even after water quality improvement, however, recovery of aquatic biological structure and function is not guaranteed and can be limited by a complexity of factors including, for example, extinction of endemic species during the eutrophication phase (Schindler, 2006; Carpenter *et al.*, 2011). Using modeling, no improvement in Baltic Sea eutrophication was predicted in response to decreased nutrient loads since the 1980s due to at least a 20-year time lag in water quality response (Gustafsson *et al.*, 2012). Further to time lags that occur in the biophysical response of waterbodies, implementation of cultural and structural changes to farms and farm practice takes time, even where measures are made mandatory by governments or industry (Kronvang *et al.*, 2008).

Observed Effects of Mitigation on Water Quality

Agricultural mitigation measures have had either no measurable effect, or positive, or negative effects on water quality over periods of 3–20 years in meso-catchments in North America, New Zealand, Europe, and Brazil (Melland *et al.*, 2013). Beneficial effects occurred over periods of 1.5–10 years whereas the time it took for these effects to be measured and identified as significant ranged from 4 to 15 years. These response times tend to increase with increasing catchment size. An increasing number of studies have integrated measurement of environmental impact in terms of biological water quality (Bergfur *et al.*, 2012) along with the more traditional hydrological and chemical indicators. In most catchments where beneficial effects of mitigation measures were successfully measured, combinations of measures that address nutrient or pollutant sources, pathways, delivery, and impact have been implemented. Successful farm measures included improved engineering and crop management to reduce runoff and drainage of nutrients and sediment, as well as high rates of implementation of measures across the catchments. In many cases, the potential to measure improvement in one or more water quality indicators was limited by the impact of a few management or weather events. Reasons that water quality did not improve in some studies included the uncertainty inherent in most nutrient flux measurements and a lack of high flow water quality samples that limited the ability of practice impacts to be measured. In other catchments, it was difficult to verify whether a lack of effect was the result of ineffective measures, or because time lags for improvement of water quality were longer than the monitored period. Pollution swapping was identified in some cases. A number of meso-catchment studies attribute water quality improvements largely to changes in land use from a more intensive system such as maize strip cropping to a less intensive system such as alfalfa or due to retirement of land from production altogether (Schilling and Spooner, 2006; Yates *et al.*, 2007; Makarewicz *et al.*, 2009). Where land is taken out of production, or where land use intensity is reduced to mitigate water quality impacts, a potential trade-off between water quality and agricultural output may occur. In contrast, and although environmental water quality targets have yet to be met (Windolf *et al.*, 2012), measures including setting minimum plant-available nitrogen percentages for manure nitrogen, and capping livestock density and allowable nitrogen fertilizer rates in Denmark, have led to a significant decrease in nitrogen concentrations in 84% of monitored streams (Kronvang *et al.*, 2008) and at the same time, crop yields have been sustained and livestock production has increased.

Sustainable Intensification

To feed the world's population, which is projected to increase to 9 billion in 2050, policies enabling 'sustainable intensification' are being promoted (Foley *et al.*, 2011). Sustainable intensification has been defined as "simultaneously raising productivity, increasing resource use efficiency, and reducing negative environmental impacts of agriculture" (Bolton and Crute, 2011). For example, De Klein *et al.* (2012) identified, through modeling of a database of farm system information, that by incorporating targeted mitigation strategies into pastoral dairy production systems increases in milk production without a concomitant increase in nitrogen leaching and greenhouse gas emissions is theoretically possible and needs to be tested in the field. Currently, there are few catchment-scale examples that demonstrate increased production and economic wealth while simultaneously maintaining high-quality surface waters in intensive agricultural settings, highlighting that sustainable intensification remains a continuing challenge.

Summary

All human activities, including agriculture, have an impact on the quality and quantity of freshwater resources. In turn,

maintaining good water quality is imperative for supporting human use of freshwater and sustaining ecosystem function. Agricultural activities can impair water quality through excess movement of soil, nutrients, salt, pathogens, and chemicals from land to water. When reaching waterbodies in excessive amounts, these often-essential components of agricultural systems can be considered pollutants. Plot and field-scale studies have identified a range of technical options that can mitigate off-farm water quality degradation and many options also improve the profitability and sustainability of the farming system. These technical options include limiting the source of pollutant that is available for transport, managing the pathways of travel that a pollutant takes before reaching the waterbody, reducing direct inputs of pollutants into a waterbody, and directly manipulating the waterbody where an impact has occurred.

To maintain or achieve good water quality in agricultural catchments, policies and management recommendations should be developed after consideration of the likely implementation rates (which includes an assessment of cost) and effectiveness of the practices. Consideration of the potential for pollution swapping is also necessary. Headwater river catchments provide useful spatial scales for measuring the effectiveness of practices because these catchments represent the complexity of activities and transport pathways occurring in agricultural landscapes. Catchments are also increasingly used to define administrative boundaries for water resource management. The cost, difficulties in monitoring and collecting information, uncertainty in relating cause to effect, and the long time frames needed to measure changes at these scales is challenging. There is, however, a growing body of evidence that water quality can be improved in intensively farmed landscapes. These studies, and other scientifically robust monitoring and modeling endeavors, are important for informing effective, socially acceptable, and cost beneficial strategies that can facilitate sustainable intensification of agriculture into the future.

Land Use, Land Cover, and Food-Energy-Environment Trade-Off: Key Issues and Insights for Millennium Development Goals

GG Das, Hanyang University, Kyunggi-Do, South Korea

© 2014 Elsevier Inc. All rights reserved.

Glossary

Computable general equilibrium (CGE) A computer-simulated neoclassical macroeconomic model based on microfoundations of optimizing behaviors of representative agents, viz., firms, consumers, and governments. Typically, these are used for practical policy modeling of tax, trade, tariff, technology, and policies, among others. It uses popular software, like general algebraic modeling system and general equilibrium modeling package for model implementation.

Global trade analysis project A project housed in the agricultural economics department of Purdue University, West Lafayette, IN, USA. This is a trade model with 57 single and composite sectors with 129 regions (Version 8 of the database). It has 29 agency members, including the World Bank, US International Trade Commission, the Massachusetts Institute of Technology joint program on the Science and Policy of Global Change, and European Commission, among others.

Human capability The capability approach to economic development is pioneered by Nobel Laureate Economist Amartya Sen (Indian National, currently professor of Economics at Harvard University, USA) in the 1980s and developed further in the 1990s. It gave a new dimension to traditional welfare economics by broadening the definition in terms of functioning, entitlements, agency, and human development. The United Nations' human development index and the inclusive wealth index make extensive use of this aspect of human capability where 'freedom' from poverty, deprivation, and any form of degradation is of central importance. Thus, it is multidimensional in nature and could be useful for issues of food and nutritional security linked to land use and climate changes.

Immiserizing effects 'Pauperizing' effects of any policy. It was discussed in the context of trade-led growth. If a growth does not serve the purpose of benefiting the targeted poor, then the effect of such policy is said to be immiserizing. In case of land rush deals, the immiserizing effects refer to the adverse deleterious effect on the landless or marginal landholder of land acquisition for growing food–biofuel crop and feed and reexporting them.

Input–output model Usually known as I–O model, it shows interdependences between sectors of a national economy and different regions. It was developed by Wassily Leontief, and he was awarded the Nobel Prize for his contribution in this area. This is the basis of social accounting matrix and CGE models showing interindustry structure via intersectoral linkages in a square matrix form. It gives a linear system of equations from which solutions for final output, intermediate output, and input–output coefficients are obtained by satisfying Hawkins-Simon condition of nonnegative principal minors for Leontief inverse matrix.

Land rush Since 2009 especially, fueled by food–feed–fuel competition and food crisis, many countries were involved in land acquisition in other countries, such as Madagascar, Cambodia, Pakistan, and Ethiopia, among others. China, South Korea, India, and other emerging economies were active. This is called 'land grab' where most of these countries acquired farmland (and water resources) to grow crops and exported back to their country for consumption (often, it was called land outsourcing by 'The Economist' magazine). This created civil conflicts, riots, disturbances, and political backlash in many destination countries.

Millennium development goals Established by the Millennium Summit of the United Nations in 2000, it has eight goals for development, each having different targets to be achieved by 2015. As it is nearing the target year of 2015, evaluating these goals and achievements is need of the hour. In brief, these goals are the following: halving the extreme poverty, universal primary education, gender balance and women empowerment, reducing child mortality, maternal health improvement, environmental sustainability, and global partnership for development. Until 2013, the progress was uneven across regions.

Social accounting matrix (SAM) The backbone of the CGE model (described above). Every country's SAM captures the flows of major economic activities between agents, viz., firms, households, government, and rest of the economy with expenditure–sales flows, and corresponding flows in a matrix format based on National Income Accounts of a nation. Normally, every country brings out SAM for a particular year and hence it offers a static picture of the economy and is benchmarked so that row and column sums match. Column and row number entries add up to match. The United Nation (UN) standardized national accounts is the basis of extended SAM analysis and SAM multiplier under different scenarios.

Land and Land Resources refer to a delineable area of the earth's terrestrial surface, encompassing all attributes of the biosphere immediately above or below this surface, including those of the near-surface, climate, the soil and terrain forms, the surface hydrology (including shallow lakes, rivers, marshes and swamps), the near-surface sedimentary layers and associated groundwater and

 doi:10.1016/B978-0-444-52512-3.00081-4

> geohydrological reserve, the plant and animal populations, the human settlement pattern and physical results of past and present human activity (terracing, water storage or drainage structures, roads, buildings, etc.). (FAO-UNEP, 1997)

> Global demand for agricultural land is on a collision course with environmental protection goals. We face a 'perfect storm' as we struggle to feed a burgeoning population on a diminishing supply of land, water, nutrients, and biodiversity. Despite global efforts, ambitious targets and massive expenditure, there are as yet no general and effective solutions for meeting both nature conservation goals and human needs. (Sayer *et al.*, 2013)

Introduction and Overview

The first quote that opens up the article suggests that the global economy is embedded in the earth's ecosystem and land use and cover is an essential element in ecological economics. On a different note, the second quote gives a cautionary message that land-use practice (e.g., deforestation, grazing, and agriculture) affects ecosystem, biodiversity, and climate and impacts on land cover. The crucial point is, however, anything associated with 'land' involves emotive issues. Anything disrupting its ownership, inheritance, and the change of land-use patterns is bound to create complex problems that could hardly evade one's attention. Economic development depends on land allocation as history of economic thought informs one since the days of the physiocrats who placed immense importance on agriculture sector as the primary source of value and later Ricardo (2004) [1817] expounding rent on land as reflective of its quality. Although the modern era has placed emphasis on industrialization and service sector growth, and land has attracted less than deserving attention, the issue is complex but challenging in its own merit. Green growth or economic development with low carbon emissions has been of immense research interest and great concern among the policy makers. Several factors cause the unprecedented rise in the level of the global carbon emissions and result in change in the status of habitat as well as natural resources. These are as follows: human impact, population growth, fossil fuel combustion, land-use changes, and natural resource depletion, to mention but a few. Vollan and Ostrom (2010) argued that:

> Sustainably managing common natural resources, such as fisheries, water, and forests, is essential for our long-term survival. Many analysts have assumed, however, that people will maximize short-term self-benefits…and warned that this behavior will inevitably produce a 'tragedy of the commons.'

An 'inclusive' approach is needed to understand the impact mechanisms of land use and forestry policies on macroeconomic variables, climate change, and food perils. Thus, it warrants a shift in the paradigm of economic development, based on sustainability and harmony or balance between economic growth and natural resource base. The issue of land use is fundamental to climate change, agricultural production, forestry management, bioenergy, and ownership and property rights tangled with recent rush for land acquisition (land grab and water grab). Food crisis and climate crisis are interrelated, if not two sides of the same coin, i.e., the aspect of natural resource management (NRM) in the broad sense of the term. The rising levels of traces of atmospheric greenhouse gases (GHGs), especially that of carbon dioxide, through greenhouse effects threaten a natural climate control system mechanism that maintains planet Earth's average temperature hospitable to living creatures – plants and animals. With escalation in the level and concentration of the GHGs, like methane, nitrous oxide, ozone, and carbon dioxide, the stability of this natural resource is jolted and the whole ecosphere is facing crisis. Synergistic combinations of climate change and land-use changes have potential to produce dramatic impacts on land cover.

Of late, no other issue has received more attention than the problems of climate change, food perils, global food insecurity, and spiraling of world food prices. Price spiraling in the food and feed stocks is inducing policy makers in developed and developing nations to rethink current agricultural, environmental, and trade policies. Climate change, food perils, global food insecurity, spiraling of world food prices, and economic crisis are affecting humanity. Recent food price crisis starting from 2008 till now shows that hunger and deprivation still remain a key challenge despite rise in agricultural productivity, and the millennium development goals (MDG) are not achieved in terms of balancing sustainable socioeconomic and environmental development and access to food. Global unrest and upheavals over food and feed prices have called for attention into the debate surrounding the food–feed–fuel trinity. With the onslaught of globalization and emergence of Southern Engines of Growth (e.g., Brazil, Russia, India, China, South Africa, and Mexico (BRICSAM) economies and rapidly growing dynamic emerging economies), what is driving the recent variability of land use is the increasing competition for land between burgeoning demand for food crops and growing energy crops based on biofuels. Less reliance on fossil fuels (coal, oil, and gas) and increasing reliance on renewable and environmentally sustainable energy or bioenergy are of paramount importance. In the face of fluctuating oil prices, more emphasis is on investment in innovation technologies related to renewable and environmentally friendly diverse energy mix (for instance, solar, wind, or biomethane power) and preventing depletion of natural resources at the same time. Development needs to be environment-inclusive with a focus on biodiversity. Obviously, this involves efficient management of natural resource, viz., land, coal, oil, and gas – the last three being the major source of fossil fuel combustion leading to emissions. Complex interplay between energy demand, economic growth, greenhouse effects, climate change, and food crisis needs a better multidimensional perspective for its pivotal role in poverty alleviation, human development, and inclusivity. Therefore, the role of agriculture and forestry for development gains due importance as the deadline of MDGs approaches soon, and needless to say, the issue of 'land use and land management' also deserves attention.

Spence Commission on Growth and Development Report (World Bank Commission on Growth and Development, 2008) and World Development Report (World Bank, 2008) have also emphasized on the preponderance role of climate issues and food security amidst unprecedented growth in

demand fueled by economic prosperity and inequality. According to Dell *et al.* (2008), mean global land temperatures have gone up by 1 °C with disparate warming effects across nations. Also, they showed that this affects growth rates and levels in poor countries more than the rich nations. Interestingly, they show the effect of socioeconomic and institutional factors in the wake of such climatic shift causing changes in soil quality, water/sea levels, natural disasters, etc. Thus, an 'inclusive' approach is needed to understand the impact mechanisms of land use and forestry policies on macroeconomic variables, climate change, and food perils. The major challenge is to enunciate the national and international policy approaches to tackle the shortage of food supply without depleting the natural resource base.

If these interconnected issues are not seen in proper perspective with a unified and broader approach, the perceptible gains from economic development will be submerged. After all, the earth's most important and largest reservoir of natural resources is the global ecosphere. For the purpose of this article, the authors focus on land-use changes and environmental degradation as one of the most important causes behind food insecurity. Increasing global integration, economic growth in emerging economies, i.e., BRICSAM, land-use changes, population growth, and increasing fossil fuel usage have led to high level of global carbon emissions leading to GHG effects. This, along with the oil crisis, has led to adoption of biofuel policies. Also, enacting the law of using biofuel and diversion of crops and land away from the usage for food supply has led to food insecurity. Thus, land-use changes and conversion of forest to nonforest use have led to the overall crisis.

All these speak volumes for the necessity of an approach and scientific understanding so as to derive significant policy debate about climate change and its human impact. As Turner II *et al.* (2007, p. 20666) has mentioned:

> Land change science has emerged as a fundamental component of global environmental change and sustainability research. This interdisciplinary field seeks to understand the dynamics of land cover and land use as a coupled human–environment system to address theory, concepts, models, and applications relevant to environmental and societal problems, including the intersection of the two.

Thus, the authors further argued (p. 20667), "Changes in land and ecosystems and their implications for global environmental change and sustainability are a major research challenge for the human–environmental sciences." This emergent land-change (system) science (LCS) research community takes environment as arrays of ecosystems where land-use decisions affect structure and functioning. Sayer *et al.* (2013) had offered a 'ten principle' guidelines for a landscape approach for reconciliation of competing land uses for growing food demand, growing bioenergy demand, conservation, and the ensuing food–fuel trade-off affecting land switching for alternative uses. By viewing land use/land cover changes as a 'coupled system,' LCS models are complex involving 'environmental dynamics' as well as agent-based decision making, technological innovation, socioeconomic issues (e.g., economic crisis), and biophysical disturbances (drought causing adverse effects on food supply and famine, soil degradation, tsunami, etc.). In the similar vein, the 'landscape approach' offers a guideline, in comparison with sectoral approach based on optimization principles and decision making, for an integrated people-centric view where decision-making process has a bearing on the decision-making outcome and also agriculture–environment synergy plays a key role.

Scientific investigation on this issue involves, generally, developing a compendium of database of information for understanding land-use change and land management across regions, building up models of land-use decisions for identifying factors, understanding dynamics, and also developing integrated assessment models (IAMs) encompassing global and regional models. Different modeling approaches are in vogue for studying the effect of climate change and impact analysis. For example, impact assessment models are major framework tools for analyzing climate change policy. As bioenergy is becoming an important factor for transition from fossil fuels to carbon-free energies (in addition to solar and nuclear sources), land use needs to be integrated in analysis of climate or energy policy. Several models have emerged, one of which is the computable general equilibrium (CGE) model that integrates land use changes in economic decision making in a neoclassical mainstream framework involving optimization exercises of economic actors, viz., producers or firms, consumers or households, and governments in a 'global trade analysis project (GTAP)' model. These models are insightful with deficiencies. As Pindyck (2013, p. 860) had said:

> A plethora of Integrated Assessment Models (IAMs) have been constructed and used to estimate the social cost of carbon (SCC) and evaluate alternative abatement policies. These models have crucial flaws that make them close to useless as tools for policy analysis: certain inputs (e.g., the discount rate) are arbitrary, but have huge effects on the SCC estimates the models produce; the models' descriptions of the impact of climate change are completely ad hoc, with no theoretical or empirical foundation; and the models can tell us nothing about the most important driver of the SCC, the possibility of a catastrophic climate outcome. IAM-based analyses of climate policy create a perception of knowledge and precision, but that perception is illusory and misleading.

Also, Vollan and Ostrom (2010) called for analytical research and empirical verification with a 'behavioral theory of human action' by incorporating 'microsituational' and 'broader contextual variables' for explaining cooperation in common resources.

In this article, the author addresses land use and land-use changes from the broader perspective of food perils and climate change causing vulnerability to humanity at large. As this aspect is dealt with in another part of the encyclopedia, the author does not discuss in detail about vulnerability and adaptation; however, in this article he situates the discussion in the wider context of: (1) triple crisis, (2) land-use changes induced by several drivers (e.g., economic growth, energy policy, etc.), and (3) land reforms and land acquisitions. Thus, this article purports to offer distinctive information maintaining continuity of broad themes of the book. In particular, the author has reviewed studies dealing with the aspects of land-use changes, land grab, and climate change from the angles of: (1) practical policy issues and (2) analytical studies modeling the interlinkages. Quite distinctively, this article differs from other articles dealing with different aspects of land

use, such as management, restoration, biodiversity, and conflict between agriculture and urban sprawl. Section Land Use, Land Cover: Reconciliation of Issues and Evidences offers a synoptic overview of basics of land use and land cover (LULC), and driving forces underlying changes in them are discussed in Section Proximate Causes behind Recent Land-Use Changes: Food–Energy–Environment Trilemma, whereas Section Changes in Land Use and Energy–Food Security Trade-Off: From the Perspective of MDG spells out the consequences of such changes in terms of global warming and food security. Section 'New' Lands: Myths and Realities of Land Deal discusses current spate of global land deal and aspects of land acquisition for economic development in some developing nations. The modeling lens of analysis of such issues offers snapshot view briefly in Section Land-Use and Land-Cover Change through the Modeling 'Lens': A Bird's Eye (Re-) View; Section Concluding Observations concludes with some highlighted challenges to date.

Land Use and Land Cover: Reconciliation of Issues and Evidences

Most of the land-use decisions based on economic considerations take into account the market values of land and such decisions could lead to damages to ecosystem services, such as reduction in land for wildlife habitat or recreational space or more GHG emissions leading to decline in human welfare resulting in deprivation in broader connotation of the term. To weigh the benefit and loss, it is needed to adopt the people-centric view of such changes, and human-devised policies should take into account the complexity of natural environment and biodiversity for improving land-use and land-cover changes in terms of arresting climate degradation, maintaining habitat and diversity, and balancing agriculture and forestry. LULC is central to any global environmental change and central to the UN MDG for food security, as they affect food entitlements, nutrition and nourishment, and level of human deprivation. However, it is needed to get a clear understanding of terminologies without using them erroneously interchangeably. In fact, given the huge dimension of work and complex nature of envisaged interactions, as mentioned by Turner II *et al.* (2007, p. 20667),

> …the absence of a universal land-use/cover taxonomy have given rise to metaclassifications of land-use/cover and translations between different classification schemes to compare case studies and aggregate their findings.

Taxonomy: Brief Overview

Land cover refers to the earth's terrestrial surface and subsurface covered by grass, trees, water, bare ground, asphalt, soil, and human structures, etc. Conversions or modifications of such cover means replacement of one cover type by another, for example, thanks to agricultural expansion, forestry, livestock herding, agroforestry practices, deforestation, or land switching, change in the urbanization sprawl, etc. affect features of land and its inherent properties. These changes cause alterations in biodiversity, productivity, soil quality, runoff, material and energy flows in the biogeospheres, gas emissions, carbon cycle, etc. All these are triggered by human action for purposeful activity, such as agricultural expansion or structural shift, like industrialization for economic growth. Therefore, land-use changes, driven by purposeful human activities exploiting the terrestrial surface, cause land-cover changes and hence their biophysical attributes and classification status. How people make use of land and socioeconomic activities defines broadly the land-use classes (e.g., urban land use, industrial land, agricultural land-use, etc.), and the changes in such uses, depending on definitions adopted, define land-cover types and their classification. However, there is no broad consensus on uniform definitions. According to Michigan State University Extension Service:

> *Land use* is commonly defined as a series of operations on land, carried out by humans, with the intention to obtain products and/or benefits through using land resources. *Land cover* is commonly defined as the vegetation (natural or planted) or man-made constructions (buildings, etc.) which occur on the earth surface. Water, ice, bare rock, sand and similar surfaces also count as land cover … In short, land use indicates how people are using the land, whereas land cover indicates the physical land type.

However, a change in one does not imply change in other or vice versa. In other words, having same land cover does not mean same land use as the use of the same land parcel might be for different economic uses; similarly, same land use does not imply identical land cover. According to Consortium for Atlantic Regional Assessment:

> Land use refers to how land is used by humans. In other words it refers to the economic use to which land is put. For example is the land being used for commercial purposes (stores, office buildings, apartments, etc.) or for industrial purposes (factories, assembly plants)? Or is the land being used for recreational or agricultural purposes? On the other hand, land cover refers to the vegetation, structures, or other features that cover the land. For example, is the land covered by grass, by trees, by water, or by large buildings surrounded by a lawn?

Therefore, for a particular land mass, both the aspects of 'use' and 'cover' provide a comprehensive idea about the proper land management so as to facilitate planning and decision making.

To get comprehensive worldwide overviews of the status, the role of Food and Agricultural Organization (FAO) of the United Nations in collecting and disseminating information on agriculture, forestry, food security, and land use–land cover is significant. According to FAO:

> Land use is characterized by the arrangements, activities and inputs people undertake in a certain land cover type to produce, change or maintain it. (FAO-UNEP, 1999) (*Adopted during the course of development of the Land Cover Classification System*, LCCS). A more inclusive definition of land-use is often used in practice. 'Land use' actually includes near-surface water (see the definition of land). Any given area of land is usually used to satisfy multiple objectives or purposes.

The land-use information contains dimensions of action covering 'what,' where,' 'when,' and 'why' aspects behind current land-use practices. Hence, this gives ideas on factors

influencing land-use patterns. Further as per Di Gregorio and Jansen (2000),

> The Land Cover Classification System (LCCS) is a comprehensive, standardized *a priori* classification system, designed to meet specific user requirements, and created for mapping exercises, independent of the scale or means used to map. Any land cover identified anywhere in the world can be readily accommodated. The classification uses a set of independent diagnostic criteria that allow correlation with existing classifications and legends.

They use environmental and technical attributes to further refine the definition. However, due to lack of space, it is not explained in detail in this article.

Land-Use and Land-Cover Data: Overview and Current Status

Land-use practices (e.g., deforestation, grazing, and agriculture) affect ecosystem, biodiversity, and climate and impacts on land cover. To get an impression about the current status, it is important to have information about the available datasets and their coverage across global regions. As mentioned by Hertel *et al.* (2013, p. 6),

> Empirical analysis and operational models particularly suffer from the lack of data. Nordhaus (2006) is a first step towards spatially explicit economic data. In the meantime, spatial down-scaling techniques are also being developed to generate gridded socio-economic data from regional aggregates. Validating these methods against actual spatial data will be necessary for assessing performance and reducing uncertainties across alternative methods.

As seen in Section Land-Use and Land-Cover Change through the Modeling 'Lens': A Bird's Eye (Re-) View, prerequisite for a successful modeling effort depends on good quality data covering the concerned variables. Nordhaus (2006) developed Geographically based Economic Data (G-ECON) database for countries measured with a resolution of 1° latitude and 1° longitude scale covering 25, 572 terrestrial grid cells. Criticizing the modern view of economic growth fueled by capital, labor, and technology, Nordhaus (2006) thought omission of geographical and climate variables makes the discussion on economic development incomplete. His novelty was to introduce the concept of 'gross cell product (GCP)' or 'gridded output,' where grid cell is the unit of data referring to surface bounded by 1° latitude and 1° longitude area with 64, 800 grid cells worldwide. GCP is value added in a specific geographic region and summed across all cells in a country/region. It converts into gross domestic product (GDP)/gross national product. Their estimates of per capita are used in economic modeling exploring climatic and geographic impact on economic activity. According to Nordhaus (2006, p. 3510), "The G-Econ database can be useful not only for economists interested in spatial economics but equally for environmental scientists looking to link their satellite and other geographically based data with economic data." Using annual maps of cropland, pastureland, harvest of wood, and urban land as inputs, Meiyappan and Jain (2012) characterized historical LULC changes and offered datasets useful for modelers for exploring the effects of changes in LULC effects on biogeophysics, biogeochemistry, and hydrological scale, and the datasets are downloadable from a webpage. This dataset is consistent for use with Integrated Science Assessment Model (ISAM). The data coverage is reproduced from the same paper in **Tables 1** and **2**.

However, there are global databases that have been developed for climate change and biofuel policy analysis. One of them is developed by Monfreda *et al.* (2013), who described the global agricultural land-use data of the global agricultural crop and grazing lands using data fusion technique with the collaboration of the Center for Sustainability and the Global Environment at the University of Wisconsin. Sohngen, *et al.* (2013) had developed global forestry data for land-use modeling. This database and model can handle sustainability issues related to forested ecosystem. Also, an integrated land-use database has been developed on the basis of GTAP CGE model by extending to incorporate 18 agroecological zones (AEZ).

Proximate Causes behind Recent Land-Use Changes: Food–Energy–Environment Trilemma

Typically, cross-sectional analyses (a posteriori) and detailed case studies (a priori) explored the reasons for land-use/

Table 1 Result of average estimates (in million km^2 units and rounded to one decimal places) of cropland and pastureland areas for 2001–05 based on datasets, as cited by authors, viz., RF (sourced from Ramankutty and Foley, 1999), HYDE (based on Klein Goldewijk *et al.*, 2011) and HH (based on Houghton, 2008)

land-cover changes. For example, in different contexts, generally it has been found that deforestation, desertification, agricultural expansion and intensification, industrialization, urban sprawl, forest degradation, fossil fuel demand, etc. lie behind changes in LULC. Generally, proximate causes are direct causes related to actions of individual households, communities, farms recurrently affecting agriculture, forestry, and infrastructure (e.g., road, irrigation, etc.). The core causes underpinning them that trigger a chain of drivers are as follows: demographic, technological, economic growth, environmental factors like tsunami, cyclone, drought, energy crisis, socioeconomic and institutional factors, and biophysical variables. Distinctions between these variables are often blurred as web of factor work conjointly. Separation of exogenous factors and endogenous variables are often difficult. Ojima *et al.* (1994) offered a link between human action and LULC changes via land-use decisions (economic aspect) and biophysical factors (environmental aspect). According to Geist and Lambin (2002), the land characteristics-related biophysical features that impacte on forest conversion, deforestation, and modifications are as follows: soil quality, watercourse, vegetation, topography, forest fires induced by drought, and weed intrusion. The features can further be extended to climatic variability, like rainfall trends and changes in fire regime, dry/wet conditions, and matter for dry land zones such as Sahel or Senegal. In the case of cropland, McConnell and Keys (2005) had found that precipitation, soil fertility, erosion, and vicinity of watercourse matter for agricultural production intensification, often leading to land diversion from one location to another as those biophysical factors change. (Poverty often underlies the incidence of deforestation as nonrich people are involved in forest fragmentation, logging, fossil fuel use, and other activities disturbing bioecosphere (see Geist and Lambin, 2003)). On the basis of household surveys and expert interviews, Qasim *et al.* (2013, p. 146) had found evidence that 'technological and environmental factors, accessibility and proximity to local markets, immense use of firewood, conflicting property rights and other institutional weaknesses, and overgrazing of alpine pasture were the main driving forces for agriculture expansion and deforestation.' The study corroborates the conjecture about the factors affecting land-use changes in developing nations, but for policy insights the author felt the need for framework of a multisectoral, multiscale approach.

For the economic factors and policies, the complex web of interactions among variables, such as input and output prices, subsidies to agriculture, taxes, transportation cost, fertilizer cost, capital flows, credit access (e.g., via rural credit market or microfinance recently), technology, and land reforms, work together to affect land-use pattern and land relations. (In this article, for want of space, issues like land acquisition, share cropping, share tenancy, landless laborers in agriculture, or dual economy surplus labor case that are seen in developing economies like India, Bangladesh, Pakistan, or some Asian nations, are not discussed. These issues are so interesting and complex that they deserve a lengthy discourse, which is beyond the small volume of an article). Mostly, demand-driven causes boosted by recent economic growth, especially in Southern Engines of Growth (e.g., BRICSAM), have triggered a change in conspicuous consumption habits with diversion from cereals to cash crops or even dairy or meat products. Also, the Green Revolution (agrotechnological innovation) has led to the emergence of capitalist farming with high-yielding variety seeds, requiring different input combination as compared with subsistence farming. As Geist and Lambin (2002) had discussed, in Asia, Africa, Latin America, and in most of the regions, forest conversion and land degradation in dry land or cropland have been triggered by economic and technological factors, such as market growth, commercialization (consumption demand surge, sectoral diversification with economic growth, and structural transformation), market failures and nonmarket benefits (like conservation easement, agroforestry, ecotourism, etc.), urban industrial expansion, biotechnological change (biotechnology, GM Crops, Fertilizer, and Pesticide), poor timber/wood extraction techniques, economic deprivation and impoverishment, deficiencies in technical knowledge, and absorptive capacity (Das and Alavalapati, 2003; Das, 2007). Different geographical regions have different contributory factors. For example, in sub-Saharan Africa, changes in livestock practices, replacement of grazing with cropping, land intensification (operating at the intensive margin of land), access to capital and insurance markets, public investment in technology, water management, etc. played a role. However, in case of Latin America, as McConnell and Keys (2005) mentioned, market-driven agricultural expansion, technology adoption, shifting to new crops, credit market functioning and infrastructure (road and irrigation), etc. played a role. In contrast, for Asia, similar factors work, but more important role could be ascribed to adoption of agroforestry practices, land tenure structure, large-scale irrigation, frequency of cultivation and growth of

cultivars, labor bottlenecks, change in urban consumption habits due to economic growth, and agricultural policies like subsidies, tax, credits given to farmers with poor background, etc. in all these regions, phases of industrialization, and more recently, the service sector-led growth has caused dramatic shift in macroeconomic structure causing agriculture to shrink considerably. This causes changes in land use and land ownership, resulting in income distribution effects (see World Bank: World Development Report 2013 for grand overview of income inequality and occupational displacement in a macroeconomic context). (As this article introduces related aspects of land-use changes, discussion of this aspect is the subject matter of separate topics in the discipline of economics of poverty, income distribution, and inequality in the wake of structural changes. This does not undermine the purpose as the author touches on the important aspect for benefit of readers' familiarity with the important issue at this juncture of globalization and economic crisis inflicting rich and nonrich alike.) Demographic factors like population explosion in countries like India and China are a matter of concern; furthermore, aging population is another concern. Starting from Malthus (1798) and followed by Ehrlich and Holdren (1971), the negative impact is emphasized with controversial debate.

With global interconnectedness via trade and foreign direct investment, increase complexity and uncertainty looms large. For example, trade in forest products, rangeland modifications, urbanization led by migration, eco labeling and global organic food networks, trade in GM goods, land rush where foreign production is outsourced in the less-developed countries like Africa (Das, 2013) affect biodiversity via land-use changes (Geist *et al.*, 2006).

As Godfray *et al.* (2010, p. 812) had argued:

> Continuing population and consumption growth will mean that the global demand for food will increase for at least another 40 years. Growing competition for land, water, and energy, in addition to the overexploitation of fisheries, will affect our ability to produce food, as will the urgent requirement to reduce the impact of the food system on the environment. The effects of climate change are a further threat. But the world can produce more food and can ensure that it is used more efficiently and equitably. A multifaceted and linked global strategy is needed to ensure sustainable and equitable food security …

Moreover, Godfray (2011) argued that the threat of climate change and sustainability thwarts development and accentuates food crisis, pushing people more into food poverty. The need for sustainable intensification and global cooperation to close the yield gap is emphasized. Quoting Godfray *et al.* (2010, p. 813):

> Producing more food from the same area of land while reducing the environmental impacts requires what has been called 'sustainable intensification.' In exactly the same way that yields can be increased with the use of existing technologies, many options currently exist to reduce negative externalities. Net reductions in some GHG emissions can potentially be achieved by changing agronomic practices, the adoption of integrated pest management methods, the integrated management of waste in livestock production, and the use of agroforestry. However, the effects of different agronomic practices on the full range of GHGs can be very complex and may depend on the temporal and spatial scale of measurement. More research is required to allow a better assessment of competing policy options. Strategies such as zero or reduced tillage (the reduction in inversion ploughing), contour farming, mulches, and cover crops improve water and soil conservation, but they may not increase stocks of soil carbon or reduce emissions of nitrous oxide. Precision agriculture refers to a series of technologies that allow the application of water, nutrients, and pesticides only to the places and at the times they are required, thereby optimizing the use of inputs. Finally, agricultural land and water bodies used for aquaculture and fisheries can be managed in ways specifically designed to reduce negative impacts on biodiversity.

Global unrest and upheavals over food and feed prices have called for attention into the debate surrounding the food–feed–fuel trinity. Price spiraling in the food and feed stocks is inducing policy makers in developed and developing nations to rethink current agricultural, environmental, and trade policies. Obviously, this involves efficient management of natural resource, viz., land, coal, oil and gas – the last three being the major source of fossil fuel combustion leading to emissions. In short, higher food prices have been fueled by many factors starting in 2008–09; for example, dry weather in critical growing regions (like drought in Australia and Ukraine), a cyclone-hit Myanmar in 2009 causing further spiraling as it was siphoning off from other sources like Thailand and Vietnam, poor yields in countries like Bangladesh (hit by floods and devastating cyclone), increasing oil prices, rising production and delivery costs, etc. These are typically the natural supply shock. Rising oil prices coupled with growing demand for fertilizer has caused rise in fertilizer prices. However, supply of fertilizer has not picked up because of oil prices. Similarly, rising prices of pesticides and fuel are factors behind soaring prices. Fertilizer shortage is another factor underlying the proximate cause of dwindling supply factor for the latest rise in food prices. Growing demand due to population expansion, biofuel-led demand for corn palm oil, natural gas supply shortage, pollution factor for chemical fertilizer based on fossil fuels, tight supply due to expensive process of expansion of production, etc. have triggered a price rise.

However, growing demand from emerging economies, especially China and India, leads to higher food prices despite being unaffected by credit crunch. Surge in world demand spurred by growing world population, higher income, diet changes, and asymmetric global expansion has fueled the price hike to such an extent that with inadequate supply the impending crisis worsens for the people with less income.

Aside from these proximate conventional supply–demand factors, the underlying causes feeding into them are the concern for environmental factors, especially the GHG emission, global warming, and environmental degradation. Also, agricultural crops like soybeans, sugar (in Brazil), and corns are increasingly used to make biofuels – biodiesel and ethanol – as transportation fuels. Subsidizing and enforcing usage of biofuels have led to their widespread use as motor fuels and, in fact, people have argued about the possible contribution of diversion of food crops to fuels in causing food perils. According to Banse *et al.* (2013a, p. 59), following an equilibrium simulation model (Modular Applied General Equilibrium Tool (MAGNET), on which more in Section

Land-Use and Land-Cover Change through the Modeling 'Lens': A Bird's Eye (Re-) View) for policies to reduce emissions from deforestation, degradation, and energy crisis, the finding is summarized as:

> [At] the global level, the EU and US biofuel policies contribute to the increasing demand for biofuel crops. But other countries, such as Brazil, Canada, India, Thailand, Philippines and South Africa, that also introduced mandatory biofuel targets contribute to an even higher extent to increasing world prices for agricultural products driven by food use for fuel. With increasing agricultural output, total agricultural area is projected to increase by 5%, while production of biofuel crops increases by around 19% indicating a more intensive production of biofuel crops at the global level. Even the strong increase in crop production in countries implementing biofuel policies exceeds domestic supply, and the imports of these biofuel crops from other parts of the world which do not implement biofuel policies are projected to increase significantly. The analysis shows that apart from direct effects of an enhanced demand for bioenergy on production and land use, the indirect effects of biofuel policies dominates. Additional production of biofuel crops within and outside countries with voluntary and mandatory biofuel policies leads to strong indirect land use changes and associated GHG emissions. The systematical variation of factor mobility indicates that the 'burden' of global biofuel policies is not equally distributed across different factors within agricultural production. Agricultural land as the pre-dominant and sector-specific factor is regardless of different degree of inter-sectoral or intra-sectoral factor mobility the most important factor and limits the expansion of agricultural production.

Many studies using simulation general equilibrium models (recursive dynamic or comparative static CGE models as discussed in Section Land-Use and Land-Cover Change through the Modeling 'Lens': A Bird's Eye (Re-) View) have found this trade-off between biofuel feed/food stock and energy demand. For example, Birur *et al.* (2008) had identified six drivers behind biofuel boom as crude oil price hike, replacement of a chemical causing pollution (e.g., methyl-tertiary butyle-ether) by ethanol in the United States, subsidies for biodiesel and ethanol in the European Union and the United States, and performed historical simulation for 2001–06 to find that there is trade-off between feed and bioenergy crops. In a similar vein, Hertel *et al.* (2013) had found in a comparative static assessment under exogenously specified biofuel expansion forecasts over 2006–35 period that under International Energy Agency's 'New Policies' scenario, biofuels account for nearly one-fifth of global land-use change over 2006–35 period. In the absence of GHG regulation, the welfare-maximizing path for global land use allocates 170 Mha to biofuel-fed stocks by 2100, with the associated biofuel accounting for approximately 30% of global liquid fuel consumption. Villoria and Hertel (2011) considered two models under alternative land demand specification to show that geographic trade patterns matter under biofuel policies for indirect land-use effects depending on elasticity parameters.

As Tilman *et al.* (2009) found in the nature of the trilemma, they emphasized the need for third-generation biofuels based on microalgae and other sources in order to avoid 'biofuels done wrong!' According to them, land-use decisions for biofuel could affect both food–feed stocks and also, via indirect land-use effects biofuels could translate into negative effect on GHG reduction (the whole purpose of biofuel demand), biodiversity loss, and further food price escalation. Therefore, they call for (Tilman *et al.*, 2009, p. 271), 'dramatic improvements in policy and technology are needed to reconfigure agriculture and land use to gracefully meet global demand for both food and biofuel feedstocks.' In a similar vein, Godfray (2010, 2011) had called for 'more sustainable food system' on the basis of global cooperation between developed and developing countries in terms of technology transfer for closing the yield gap. It is quite apt to quote Godfray and Charles (2011, p. 19846),

> Increasing prices will reduce demand, but in a complex way, because food is not any other commodity. People literally have to eat to stay alive, so, as prices in- crease, an increasing fraction of poor people's incomes will be spent on food. However, between 0.75 and 1 billion people today do not have sufficient economic access to food, and even though populations in the future are likely to be wealthier on average, significant increases in food prices will hinder or re- verse progress in reducing hunger. Thus, if we do nothing, economic forces may prevent demand from increasing as high as Tilman *et al.* (2009) expect, but chiefly because people are forced to remain in food poverty – something most people would agree is unethical and would pose grave risks for global political security.

Concerned about land-use/land-cover changes, Godfray (2010, 2011) further argued,

> Producing more food with less effects on the environment requires a radical shift in thinking by the agricultural and environmental communities. The goal for agronomists and plant and animal breeders is not now simply to increase yields but to optimize across a much more complex set of objectives, with a particular emphasis on increasing input efficiency and reducing harmful outputs. Innovation in areas such as precision agriculture, soil science, and climate-smart agriculture are urgently required to make what has been called sustainable intensification a reality. In addition, it will be critical to align market incentives to promote more sustainable food production, i.e., to internalize the costs (or benefits) of the negative (or positive) externalities. For the environmental community, a major challenge is to accept the inevitable loss of some biodiversity that feeding 9 to 10 billion people will entail and to work to develop integrated land use policies that minimize this harm.

Aside from those, increasing urban uses of land surface also diverts land from agriculture, forestry, farmland, and that affects biodiversity. By doing meta analyses of 326 studies based on remote-sensed images, Seto *et al.* (2011) had estimated an increase in urban land expansion of 58 000 km^2 between 1970 and 2000. Highest rates of expansion have taken place in emerging economies and developing countries, like India, Africa, and China, whereas for the United States, it has been the largest in total urban land expansion. According to the study, 'by 2030, global urban land cover will increase between 430 000 km^2 and 12 568 000 km^2, with an estimate of 1 527 000 km^2 more likely.' The proximate causes are various, viz., growth in per capita GDP, increasing capital flows due to global integration, population growth, land use policy, and transport costs, etc.

Without any solution in vision, this leads to deprivation, starvation, and famine. Growth in incomes has led to increasing imports and restrictions or export bans and taxes or ceilings/quotas from the net exporter, thereby restricting availability of grain supplies on international markets, tightening supply conditions, and triggering further rise. There is a need for effective social and political processes to assure biotechnology's wise and wide usage in equitable way to develop

products available publicly so that the benefits accrue to all for adaptation and adoption, especially in developing countries. The role of public research systems (national innovation systems and policy) in promoting use of these technologies to produce new crop varieties is important. "We hope that world leaders coming to Rome will agree on the urgent measures that are required to boost agricultural production, especially in the most affected countries, and at the same time protect the poor from being adversely affected by high food prices," said Food and Agriculture Organization (FAO) Director-General Jacques Diouf. It calls for support to agricultural research that serves the needs of poor farmers. To prove the Malthusian predictions wrong again, the roles of science and technology for yield and fertilization are crucial. Typically, agricultural biotechnology encompasses sophisticated technologies, like tissue culture, DNA-based genetic markers, DNA chips, and other DNA-based diagnostic techniques to identify and create new varieties of traits in crops. These have immense potentials for benefits in developing countries where access to transgenic or genetically improved crop varieties can be used as a solution for addressing the difference between abject poverty, hunger, malnutrition, and a sustainable livelihood with appropriate calorie intake. Developing genetically altered new crop varieties with more micronutrients and essential nutritional value will compensate for deficient diets in poor nations. For example, soybean-derived biofuels are healthy substitute for petroleum-based home heating fuels. Norman Borlaug had also reiterated the necessity of global cooperation and collaborative system of international biotechnology research to meet the MDG by 2015. Inventions such as soybean cultivation with zero-tillage technology, use of lignocellulose-based plant feedstock and waste biomasses for conversion into biofuels, and increasing yields of bioenergy crop production, rice, and wheat could lead to net energy gain, environmental benefits, and economic efficiency without curtailing food supplies.

Thus, the policy responses could be: shifting to higher yields via engineered crops by investment in agricultural research, better chemical fertilizer, and better seed varieties, so that there is limited agricultural runoff causing environmental damage to ecosystem. Improving productivity could ease the constraint far better than the typical tax-mix policy – even for net food importer or net exporter, the agricultural technology improvement or production shifting could ease the supply constraint in the face of severe demand constraint. If government subsidizes biotechnology research or inputs, then the technological change could help the net food importer to become net producer and supplier in medium to longer run.

Changes in Land Use and Energy–Food Security Trade-Off: From the Perspective of MDG

Historically, economic development and standards of living were governed by socioeconomic variables as well as geographic (shaping institutions) and climatic factors (Acemoglu and Robinson, 2012; Diamond, 2005). As Nordhaus (1991, 2006, pp. 3510–3511) says,

> …one of the major factors in economic development has been the movement from climatic-sensitive farming and into climate-insensitive manufacturing and services. In 1820, 72% of U.S. employment was on farms, whereas by 2004, the share was down to1.2%. … Current theories and empirical studies of economic growth today give short shrift to climate as the basis for the differences in the wealth of nations. A review of a handful of textbooks on economic development shows that climate is confined to a few lines in hundreds of pages.

Thus, any discussion on LULC changes and associated climate change is incomplete without consideration of its impact on poverty, food security, and nutritional security affected by such changes in land use and lying at the core of human development. As per the MDG and FAO's definition of food–nutrition–environmental sustainability, it is imperative to address food security as part of environmental and climate change issue as well as the issue of food/feed trade-off. Nordhaus (1991, 2006) had shown the importance of having information on geographical variable (data on GCP as mentioned in Section Land Use and Land Cover: Reconciliation of Issues and Evidences) for studying impact of geography and poverty in the African context. Hertel and Rosch (2010) had mentioned that exploring the much ignored link between climate change and poverty is 'vital for the formulation of effective policy responses to climate change.' In particular, they show that climate change impacts are transmitted to the nonrich via agriculture and hence this sector is susceptible to climate change mitigation strategies.

According to Fan (2013), approximately 870 million people (1 in every 8) are undernourished and above 2 billion people lack severe deficiencies in macronutrients (IFPRI 'Walk the Talk'). The rising food prices and resultant food insecurity have a pernicious effect on human development via health damage as well as exacerbating inequality, leading to socioeconomic disturbances. Nordhaus (1991, 2006) had shown that 'geography handicap' could explain output differences between countries like Africa and developed countries. With the newly constructed database (G-ECON), it was shown that geographic conditions (e.g., temperature, precipitation, soil, and coastal proximity) determine economic disadvantage of nations like Africa compared with the temperate regions and also estimated negative impacts on world output due to doubling of CO_2 equivalent GHG emissions. Therefore, any change that causes land use/cover to change will impact on food–energy–environment equilibrium and might cause differences in output per capita via GCP.

As is well known, instead of conventional indicators of economic progress as GDP, the United Nations Human Development Report has developed the alternative concept and dimension of 'wealth' based on human capability, access to basic rights, and entitlement as well as, income, literacy, and gender balance (see Sen, 1995). Also, the UN's University (UNU) International Human Dimension Programme (UNU-IHDP) on Global Environmental Change echoes with the same concern as expounded by Stiglitz–Sen–Fitoussi Commission Report in 2009. Therefore, UNU-IHDP and UNEP (2012) focuses on human as well as natural capital as the basic ingredient of wealth. Developing an Inclusive Wealth Index (IWI) to include a human, physical, manufactured, and social and natural capital, a new dimension has been added to the

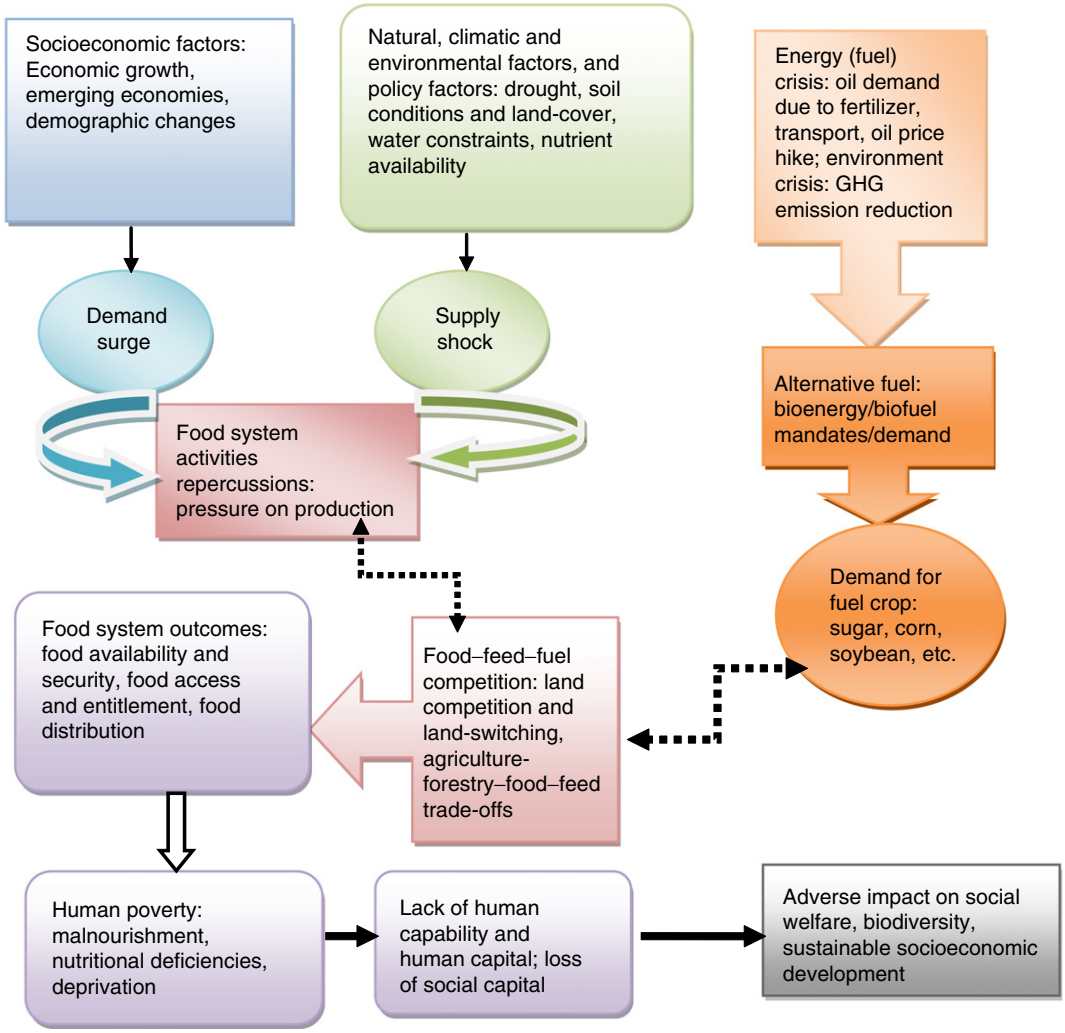

Figure 1 Drivers behind food–feed–climate change trilemma and its poverty impact.

concept of economic prosperity on a sustainable basis. As GDP is an inadequate measure, this new index captures all-round aspects of economic development. According to the report's balance sheet,

> While 19 out of the 20 countries experienced a decline in natural capital, six also saw a decline in their inclusive wealth, putting them on an unsustainable track, Russia, Venezuela, Saudi Arabia, Colombia, South Africa and Nigeria were the nations that failed to grow. The remaining 70 per cent of countries show IWI per-capita growth, indicating sustainability. 25 per cent of countries that showed a positive trend when measured by GDP per capita and HDI were found to have a negative IWI per capita. The primary driver of the difference in performance was the decline in natural capital. There are clear signs of trade-off effects between the different forms of capital.

Taking a holistic view, land-use change and climate policy could affect food and nutritional security and can endanger poverty impact. This nexus is described in Figure 1.

According to Wheeler and von Braun (2013), climate change has an adverse impact on controlling hunger and malnutrition. It hinders the progress toward a world free of hunger and deprivation. To quote them (Wheeler and von Braun, 2013, p. 508):

> Climate change could potentially interrupt progress toward a world without hunger. A robust and coherent global pattern is discernible of the impacts of climate change on crop productivity that could have consequences for food availability. The stability of whole food systems may be at risk under climate change because of short-term variability in supply. However, the potential impact is less clear at regional scales, but it is likely that climate variability and change will exacerbate food insecurity in areas currently vulnerable to hunger and undernutrition. Likewise, it can be anticipated that food access and utilization will be affected indirectly via collateral effects on household and individual incomes, and food utilization could be impaired by loss of access to drinking water and damage to health. The evidence supports the need for considerable investment in adaptation and mitigation actions toward a climate-smart food system that is more resilient to climate change influences on food security. Climate change and associated bioenergy policy will cause a shift in land-use thereby causing micronutrient deficiencies among children and adult alike. Moreover, as further emphasized, food security is illustrated by the United Nations' Food and Agricultural Organization (FAO) definition: (i) the availability of sufficient

quantities of food of appropriate quality, supplied through domestic production or imports; (ii) access by individuals to adequate resources (entitlements) for acquiring appropriate foods for a nutritious diet; (iii) utilization of food through adequate diet, clean water, sanitation, and health care to reach a state of nutritional well-being where all physiological needs are met; and (iv) stability, because to be food secure, a population, household or individual must have access to adequate food at all times. It is extremely challenging to assess precisely the current status of global food security from such a broad concept. However, the big picture is clear: About 2 billion of the global population of over 7 billion are food insecure because they fall short of one or several of FAO's dimensions of food security. Enormous geographic differences in the prevalence of hunger exist within this global estimate, with almost all countries in the most extreme 'alarming' category situated in sub-Saharan Africa or South Asia.

Following the discussion, the author offers a flow chart showing the trilemma and its impact on human development. As the diagram in **Figure 1** depicts, food security involves many dimensions, such as malnutrition, hunger, poverty, nutritional deficiencies, and promotion of environmentally sustainable green growth. As Sen (1995, p. 209) had argued: "Indeed the environmental challenge is not just that of food production – there are many other issues related to population growth and overcrowding. [In fact], a tendency to concentrate on food production only, neglecting food entitlement, can be deeply counterproductive." The diagram represents such complex holistic view.

'New' Lands: Myths and Realities of Land Deal

"Land is not just a resource to be exploited, but a crucial vehicle for the achievement of improved socioeconomic, biological, and physical environments." – Food and Agriculture Organization, United Nations (FAO) (1999), "Cultivating our Futures: FAO /Netherlands Conference on the Multifunctional Character of Agriculture and Land."

Here the author discusses the recent episodes of the rush for transborder land acquisitions in the wake of food scarcity; this is especially by emerging economic giants, with its aftermath like food riots, civil unrest, and backlash. This is linked to water grab issues, which are covered in other article in this encyclopedia. As international actors tap into lands beyond their borders, in the wake of a global systemic crises of food–feed–fuel, endangered by financial crisis, it is a contentious issue as land plays a central role in developing economies and least-developed countries, because of its insurmountable importance related to identity, property rights, livelihoods of the inhabitants, and most importantly, at this juncture, its inextricable linkages to the burning issues of the problem of 'unholy trinity' of food (in-) security, feed (in-) sufficiency, and fuel crisis (related to climate change). However, the entire picture is murky and lack of academic literature and analysis leads one to consider media reports – biased or impartial – concerning the impacts (see **Table 3**).

There are differences in size and terms of contract negotiations and often it does not involve direct land acquisitions, but rather involves food supplies via contract farming or investment in irrigation or agricultural/rural infrastructure. The latter is being welcomed to some extent, as expected, because that could generate beneficial effects to spillover to other segments (Von Braun and Meinzen-Dick, 2009). In other aspects, it has led to incidents like civil unrest and overthrow of the government in Madagascar in 2009 over the South Korean company Daewoo's attempt to acquire 1.3 million hectares for maize and oil palm; Mozambique resisted a Chinese lease deal; and some other incidents as well – to mention but a few (see Daniel and Mittal, 2009, 2010; Kugelman and Levenstein, 2009 for detailed unfolding of incidents). In this context, the author quotes Von Braun and Meinzen-Dick (2009):

Well-documented examples are scarce, and some reports are contradictory. This lack of transparency limits the involvement of civil society in negotiating and implementing deals and the ability of local stakeholders to respond to new challenges and opportunities.

It presents a table of media reports (**Table 3**) on such deals for the available range of countries, although the reports are not specific about the size of the land deals. Deininger *et al.* (2011) covers 14 countries, and it documents that the total amount of reported large-scale farmland deals sum to 45 million hectares even before the end of 2009 alone, in comparison with the average yearly rate of expansion of 4 million hectares spanning the decade up to 2008 (Deininger *et al.*, 2011, p. vi). However, all the reports unanimously agree that 'little is known so far (Von Braun and Meinzen-Dick, 2009, p. 3).' Below, the author reports the major 'observations' or evidence-based

Table 3 Examples of media reports on overseas land investments to secure food supplies, 2006–09

Country investor	*Country target*	*(Hectares)*	*Current status*	*Source*
Bahrain	Philippines	10 000	Deal signed	Bahrain News Agency (2009)
China (with private entities)	Philippines	1 240 000	Deal blocked	The Inquirer (2009)
Jordan	Sudan	25 000	Deal signed	Jordan Times (2008)
Libya	Ukraine	250 000	Deal signed	The Guardian (2008)
Qatar	Kenya	40 000	Deal signed	Daily Nation (2009)
Saudi Arabia	Tanzania	500 000	Requested	Reuters Africa (2009)
South Korea (with private entities)	Sudan	690 000	Deal signed	Korea Times (2008)
United Arab Emirates (with private entities)	Pakistan	324 000	Under implementation	The Economist (2008)

Note: A more extensive listing of media reports on overseas land investments is available on IFPRI's website at http://www.ifpri.org/ pubs/bp/bp013Table01.pdf. Well-documented examples are scarce, details on the deals are often murky, and some reports are contradictory. IFPRI invites observers to share evidence-based information on the listed and on new land deals by posting a contribution on IFPRI's blog at http://ifpriblog.org/2009/04/24/landgrab.aspx.

Source: IFPRI has compiled this table from media reports. The responsibility for the accuracy of the information presented here, however, lies with the reporting media.

information from them in order of their chronological appearances in the domain.

The study by Von Braun and Meinzen-Dick (2009) mentioned that the proliferation of land acquisitions are targeted by the countries with higher capital endowment and water scarcity (say the Gulf States) and high population with food insecurity (emerging engines like India or China) toward the host countries depending on their geographical proximity, but mostly, on the basis of their low labor cost, abundance of land and water, and favorable climate for crops. But aside from crops, biofuels (first or second generation) are also produced in these lands, causing shift in land-use patterns, and thereby defying the much-proclaimed objective motivating these deals. According to that study, approximately 15 to 20 million hectares of farmland have been negotiated or under transactions over last several years and more so. It is now at the 'systemic' crisis point. Also, Kugelman and Levenstein (2009) reported (quoting The Economist) that it is approximately one-fifth of the EU farmland and of the same size of France's farmland. (This is the study by Woodrow Wilson Centre for International Scholars on "Land Grab? Race for the World's Farmland.) Between 2006 and mid-2009, as reported by IFPRI, foreign actors had sought or secured approximately 37–49 million acres of farmland. With Ethiopia being one of the hungriest country in the world with population of 13 million, it is leasing out approximately 7.5 million acres of its fertile land to investors who are exporting food back to their own countries of residence (see Daniel and Mittal, 2009, 2010). The study by Cotula *et al.* (2009) covered qualitative interviews and case studies for five sub-Saharan African and other countries, viz., Ethiopia, Ghana, Madagascar, Mali, and the Sudan and Mozambique and Tanzania. As Cotula *et al.* (2009) mentions, "international land deals and their impacts remain still little understood."

To tackle the issue of conflicting objectives, Von Braun and Meinzen-Dick (2009) offered a 'dual approach.' First, by establishing a transparent code of conduct for the host and the foreign investors and second, designing appropriate policies by the host government to tap the opportunities and controlling the adverse effects, they fought to counter the immiserizing effects. Transparency, sharing the benefits with the locals, and adherence to national trade policies when domestic supply is at stake are emphasized. Moreover, the report mentions:

> At the root of foreign investments in agricultural land are the food crisis and the volatility in food markets that have undermined trust in trade on the side of importers. The combination of an international code of conduct, on the one hand, and improved domestic agricultural policies, on the other hand, would make a virtue of the investments that investors consider a necessity and facilitate win-win outcomes. Well-designed foreign direct investment could embed transfers of knowledge and institutional strengthening into the investment and related trade flows, thereby improving productivity in the target countries of these investments. In the longer run, a healthy trade relationship could grow out of such investment islands, building trust in trade, at least on a bilateral basis and potentially more broadly, in an increasingly volatile world food system.

According to Cotula *et al.* (2009), most of these countries lack proficient mechanism to ensure local rights, production for domestic supply over exports, protecting local interests, livelihood, and welfare and thus the 'win-win' situation should be viewed with cautious optimism rather than harping on myopic vision of potential benefits without serious study. (According to Olivier De Schutter, the UN Special Rapporteur on Right to Food, on his report to Committee on Sustainable Development: "the issue is not one of merely increasing budget allocations to agriculture, but choosing from different models of agricultural development the ones which may have different impacts and benefit various groups differently (quoted from Daniel and Mittal, 2010, p. 1).")

As emphasized by Von Braun and Meinzen-Dick (2009, p. 1):

> These land acquisitions have the potential to inject much needed investment into agriculture and rural areas in poor developing countries, but they also raise concerns about the impacts on poor local people, who risk losing access to and control over land on which they depend. It is crucial to ensure that these land deals, and the environment within which they take place, are *designed in ways* that will *reduce the threats and facilitate the opportunities* for all parties involved for a 'win-win' situation.

There are mixed reactions to the large-scale land acquisitions stemming from differences in perceived benefits as there is lack of transparency in the deal and design. As mentioned by Von Braun and Meinzen-Dick (2009), the foreign firms and the host or the 'local elites' share a commonality of interest and without the participation of the small holders or local communities. Given their underrepresentation, there is scope of 'unfavorable' terms of the deal and hence there is room for discord. The literature so far available provides evidence-based information on the pessimistic side, thus quoting Von Braun and Meinzen-Dick (2009), "unequal power relations in the land acquisition deals can put the livelihoods of the poor at risk." Whatever is the type of land – unused or unproductive under customary tenure agreements – having no formal arrangement or title to the land makes the small holders vulnerable to the deal. Therefore, by displacing from safety network of livelihood 'large-scale acquisitions jeopardize their welfare (Von Braun and Meinzen-Dick, 2009, p. 2).' (The issue of ecological diversity and sustainable development practices by the foreign investors being unaware of the local ecology and conditions are also mentioned. But, this aspect is set aside as it is beyond current scope of analysis.)

The Deininger *et al.* (2011) reiterates this apprehension that although investments could lead to higher productivity in longer run, the lack of transparency and secret or veiled tactics between the buyers and sellers (lack of governance) could be detrimental to this optimism. Thus, the report does not unequivocally lend support to the much-hyped 'benefits' of running such deal but warns against the mismanagement due to weak governance and corrupt underhand dealing. It presents evidences from 2004 to 2009 for 14 countries, mostly in Africa, and finds that 'desired benefits' were not achieved in all countries, especially in Africa where 'investments' did not achieve their full potential in terms of productivity and poverty reduction. This has been attributed to 4 factors: weak governance and failure to recognize land rights to local people, lack of capacity to manage and process large-scale investments properly, insufficient elaboration and technically nonviable investors proposals, and lack of properly formulated

development strategy to reflect development objectives of hosts and its proper focus, lack of transparency or information leaving rooms for corruption to flourish, and availability or access to information. It classifies countries on the basis of 'Yield Gaps' between actual and potential production and extent or scope for land expansion. Also, it refers to the 'significant gaps in the laws, policies, and institutions that govern such (large scale) investments' and that is the source of potential 'danger.' It calls for 'greater accountability on the part of governments and investors' and 'well-defined rights to use and occupy land.'

Moreover, by presenting a mixed picture across Africa, Latin America, Europe, and Asia, the report points out the failure on the part of most of the host governments to ensure rights to land and livelihood for the benefit of the local people and thus undermining the potential benefits via improved productivity. In fact, it mentions for some countries that there is room for potential productivity improvement on currently cultivated land, even without land available for expansion, for addressing food insecurity. Therefore, it is imperative for the host governments to make the land acquisition deals in a clear-headed and transparent way and also to invest in factors for boosting technological effort, skills, and proper institutions protecting own people. The report 'calls for a country-led approach to outside investment that sets clear criteria.' For such investments to have beneficial and sustained effect on host economies' pursuit of development, seven guiding principles have been outlined: (1) respect land and resource lights, (2) ensure food security, (3) ensure transparency, good governance, and a proper enabling environment, (4) consultation and participation, (5) responsible agroenterprise investing, (6) social sustainability, and (7) environmental sustainability. Quoting Deininger *et al.* (2011):

> Currently none of the African countries of interest to investors achieves even a quarter of its potential productivity. Rather than just focus only on an expansion of uncultivated land, it is important that investors and governments support improvements in technology, infrastructure, and institutions that can improve productivity on existing farmland.

As the World Bank (2010) mentioned, 'this debate has suffered from two main weaknesses, one among them is that there has been a dearth of rigorous, empirical analysis of what is happening on the ground (p. 1).' Das (2013) analytically, for the first time, presented a general equilibrium model capturing the immiserizing possibility of such deals.

Land-Use and Land-Cover Change through the Modeling 'Lens': A Bird's Eye (Re-) View

The preceding discussion shows that global land-use changes affect climate and is being affected by climate changes on a large scale. As human action over centuries has caused changes in land cover via land conversion for different purposeful productive activities, land-use changes need integration of agriculture, forestry, and environment with a human-centered focus. In fact, as Vollan and Ostrom (2010) mentioned, translating these 'social dilemmas' into a conditional cooperative behavior – modeled via designing via field experiment and economic games involving 'microsituational and broader contextual variables – could give valuable insights about long-term benefits of trust and cooperation in resource management. As these complex systems remain poorly understood, for practical policy implications a reasonable modeling framework to capture the interlinkages among these variables couched in terms of behavioral foundation and its subsequent empirical verification is necessary. As land-use changes cause changes in existing land cover (e.g., biofuel- or ethanol-driven conversion of cropland for sugarcane production in Brazil or India due to rise in demand for fuel for energy security leads land surface to change), it could result in atmospheric changes via variations in radiation forcing. Thus, any modeling effort for climate change policy must incorporate a land-use aspect. Below, the author gives a brief overview of major types of modeling efforts and their main thesis, without indulging in describing detailed structure and desiderata and classification of genre of models, so as to get a glimpse of distinction between modeling approaches. (Each of these models is so huge, multifaceted, and wider in scope that it is not worth evaluating each of them separately in one single article, as it goes beyond its scope. Each of them deserves separate discussion articles for their own merits (or points of demerits giving emergence to a variety of models from the breeding ground of respective criticism of each other). However, given the current focus (and length) of this article, this does not undermine the purposes at all. Given the immense practical and policy relevance, literatures abound in this area.)

According to Lambin *et al.* (2006, p. 5),

> [The] complexity of causes, processes, and impacts of land change has so far impeded the development of an integrated theory of land-use change. The need to distinguish between land-use and land cover to account for interactions between socio-economic and biophysical processes is one source of complexity. Moreover, land-use change processes are dominated by multiple agents, multiple uses of land, multiple responses to social, climatic and ecological changes, multiple spatial and temporal scales in the causes of and responses to change, and multiple ties between people and land. Causes and consequences of land-use changes depend on the social, geographic and historical context. Theory building has thus been-and still is-a difficult task.

Although no unified theoretical framework has emerged or even is possible to capture such complex interaction between socioeconomic and biophysical mechanisms and systems, the quote vindicates the necessity of a framework for analyzing LULC. Emergence of a box–arrow framework based on Turner *et al.* (1995) has shown qualitatively the linkages between social systems, ecological systems, land management, and LULC systems in a less-cluttered but informative theoretical framework. (see Lambin *et al.* (2006, p. 6)). There are other theories as well, such as multiphasic response theory (incorporating demographic changes on land-use pressures and economic responses) and complexity theory (based on complex holistic systems integrating the 'pixels' of relevant societal elements with focus on nonlinear relationship between components and their feedbacks to generate divergences from original to induced equilibrium changes in response to perturbations). LCS, as Turner II *et al.* (2007) mentioned,

simultaneously deals with human–environmental–geographical information (via remote sensing science) in an interdisciplinary, 'multiscaled coupled system' in an intensive way. Further, they (Turner II *et al.*, 2007, pp. 20667–20668) found, "Comparative and meta analyses of place-based land change studies have demonstrated the roles of such factors as markets, policy, transportation, governance, and household life cycles on different types of land covers." Therefore, they argue for inclusion of 'ambient factors,' such as biogeosphere-related variables affecting socioeconomic variables. Undoubtedly, this affects the human development through a multiplicity of channels, and to meet the MDG targets one needs to consider all the factors that might cause deprivation via food–feed availability and access, entitlement to land and food, and land degradation, drought, or desertification that intensifies the environmental channel of poverty impact.

The diversity of modeling approaches, as discussed, are driven by the need for addressing deficiencies of each model and also wide range of research agenda focusing on regional, national, or global level. Some of the models, dealing with different issues and research questions (but broadly focusing on environment–forestry–agriculture–LULC aspects), are as follows: deforestation models (Lambin and Ehrlich, 1997, Lambin and Geist (2003)), integrated urban models (U.S. Environmental Protection Agency (EPA), 2000), multiagent modes, (Bousquet and Le Page, 2004), biogeochemistry and biogeography models (VEMAP, 1995), the process-based terrestrial ecosystem model, and static and dynamic versions of global CGE model, such as dynamic timber supply model Sohngen and Mendelsohn (1998), Dynamic future agricultural resources model (FARM) (Ianchovichina *et al.*, 2001), Dynamic GTAP (GDyn, Das (2003, 2007), GTAP-E (Burniaux and Truong, 2002), Cintrafor Global Trade Model, the US Forest Services' timber assessment market model – aggregate timber land assessment system model, and last but not least, the nonlinear spatial equilibrium market structure-based sectoral Forest and Agricultural Sector Optimization Model. Unlike nonspatial models like Sahelian land-use (SALU) dealing with rate and magnitude of LULC, the spatial models like conversion of land use change and its effects (CLUE) model and geographical modelling (GEOMOD) consider pixels in spatial entities to consider spatial land-use changes owing to social and biophysical environmental changes. With regard to temporal dimension covering path dependencies, the temporal dynamics underlying land-use systems give projections or forecast over long-run LULC changes. Thus, there are static (comparative-statics comparing two snapshot equilibrium scenarios of policy impacts) models, like GTAP or regression models, and dynamic model versions, like CLUE, GEOMOD, FARM, or GDyn. Some of these models are descriptive (i.e., simulating the LULC system's functioning and future patterns of such changes), whereas others, based on the objective function of optimal land-use configurations given actual constraints of LULC and socioeconomic objectives, are prescriptive in nature and often take an agent-based bottoms-up approach (Verburg *et al.*, 2006; Piggott and Whalley, 1985; Lee *et al.*, 2013).

Verburg *et al.* (2006) mentioned that the land-use/land-cover (LUCC) project took the onerous task of developing a new generation of such models 'capable of simulating the major socioeconomic and biophysical driving forces' underpinning them with a spatial and temporal dimension. This kind of models takes a land-use systems view to include factors influencing land-use variables, such as economic, social, cultural, political, institutional, and biophysical. Most of these models are computer models performing simulation of policy scenarios on a 'what if' basis. Therefore, policy configurations affecting land-use/land-cover changes could be analyzed and their sensitivity could be tested to learn about impact.

The landscape approach is one approach to deal with these issues of competing land demands and climate change mitigation. According to Sayer *et al.* (2013, p. 8349),

> [it] seeks to provide tools and concepts for allocating and managing land to achieve social, economic, and environmental objectives in areas where agriculture, mining, and other productive land uses compete with environmental and biodiversity goals. [It] has been refined in response to increasing societal concerns about environment and development tradeoffs. Notably, there has been a shift from conservation-orientated perspectives toward increasing integration of poverty alleviation goals.

Thus, 10 principles (viz., continual learning and adaptive collaborative management, multiple scales to address diverse ranges of issues, multifunctionality of components and trade-offs, multiple stakeholders, logic and legitimacy of action via transparency, clear rights and responsibilities for conflicting claims, monitoring and participation, system-level resilience to threats and vulnerabilities of landscape, learning and improving stakeholders' skills and capacity to participate, etc.) of this approach emphasize achieving synergies between conservation and economic interests. According to this study, the typical sectoral approach is inadequate and hence 'optimal' solutions based on quantitative analyses might not capture the trade-offs between agricultural expansion, environmental change, and land competition. Models differ in terms of units of analysis – pixels or spatial units of parcel of land, individual interacting agents, and/or organizations – depending on the research questions and human–environment interaction to be analyzed.

Following the review of Turner *et al.* (2007), it can be said that LCS-based models are many. These include the following: Integrated Model to Assess the Global Environment capturing human–environment interface, CLUE model, and SALU model. However, there is agent-based modeling of individual decision making and interactions (conflicts or cooperation), statistical modeling linking household survey data with remote sensing-derived land-cover data, and simulation models where environmental change (exogenously occurring or endogenous in the system) and its impacts are analyzed under different counterfactual experiments. Integrating agent, or microeconomic units-based model with other methods, is an eclectic paradigm that is difficult to 'translate into useful land-change outcomes (Turner *et al.*, 2007, p. 20670).' For example, using explicit Dynamic Integrated Model of Forestry and Alternative Land Use, Rokityanskiy *et al.* (2007) modeled the effect of carbon sequestration policies inducing land-use and land management changes of landowners on climate change mitigation. They achieve the objectives by integrating emission scenarios and their dynamic development with the Model for Energy Supply Strategy Alternatives and their General

Environmental Impact, which operates with food security constraints and urban land usage. In particular, their findings suggested that landowners are motivated to afforestation and biomass usage substituting for fossil fuel consumption, and this results in land-use changes (i.e., via avoiding deforestation or conversion of forest land to nonforest usage) depending on carbon prices.

Among the climate change and energy models, IAM is a widely used framework. It is pluridisciplinary based on environmental science and policy modeling. It integrates knowledge from multiple domains into a single analytical framework and makes assessment or evaluation to decipher policy-relevant information on the basis of numerical model solutions. There are other models, such as simple climate models, three-dimensional more complex atmosphere–ocean general circulation models, and earth system models (ESMs), as well as coupled dynamic global vegetation models, to take into account global terrestrial carbon cycle and climate interactions. Another model for evaluating the regional and global effects of GHG reduction policies is based at Stanford University and it is a model for estimating the regional and global effects of GHG reductions. Several submodels include domestic and international open economy, emissions related to energy and nonenergy emissions of GHGs, and market and nonmarket damages due to global climate change where each economy is modeled neoclassically with Ramsey–Solow model of long-run economic growth (these models are solved using GAMS library, e.g., CONOPT3, or MINOS). All these models' successes depend on transparency and validations. Typically, these models are based on multitude of assumptions on biosphere, land use and cover, fossil fuel usage and GHG, technological progress, and future evolution of global economy. These are large scale, complex, and purport to integrate natural and social systems by quantifying different aspects, which are not amenable for quantification.

In a review, Parson and Fisher-Vanden (1997) mentioned that such models seek to 'combine knowledge from multiple disciplines in formal integrated representations' by combining socioeconomic and biophysical processes, human activities, and dynamics of human-induced emissions and their regulation. Challenges such as broadening disciplinary knowledge and informed policy and decision making have been reviewed. In another article, Van Vuuren *et al.* (2009) emphasized the necessity of understanding the uncertainties associated with quantification in the IAMs as these models are regularly used for evaluation of policies aimed at emissions controls. They consider various carbon cycle components and climate systems across different IAMs and compare them with ESMs. They find that although outcomes are more or less within ranges, large differences make them not so good for policy advice, and there is room for improvements for IAMs, for example, in terms of climate sensitivity, inertia in climate response, and carbon cycle feedback. The need for better communication between the IAM and the ESM development communities is stressed. Further, Van Vuuren *et al.* (2009) concluded:

> Given the uncertainty in climate feedback onto the carbon cycle, we recommend that IAMs should consider including these feedbacks in their uncertainty analysis. Our results also suggests a very pressing need for the climate modelling community to run their more complex, earth-system models for scenarios with aggressive mitigation and lower emissions than the IPCC SRES range, including scenarios where the concentration overshoots the eventual target level. This is because even the simple climate models cannot hope to capture the complex geographical nature of carbon cycle changes and local feedbacks, such as those involving local hydrology changes which are believed to have a significant interaction with local vegetation. The recent IPCC AR5 assessment will involve such ESM simulations, but it is important these are made available to the IAM community as early as possible. Finally, it is vital that policy makers, especially those involved in UNFCCC negotiations, are made aware of the large spread in the climate and earth system components of IAMs. More work is recommended to understand how these affect the economic outputs from current IAMs.

Another genre of model is the Integrated Global System Model (IGSM) based at Massachusetts Institute of Technology in the Joint Program on the Science and Policy of Global Change. As before, IGSM deals with human–climate system interactions and explores consequences for environment of global climate change.

The IAMs linking ecological and economic aspects of LULC got its boost from the Intergovernmental Panel on Climate Change (IPCC, 2001), which focused on improving global model analytics, integrating mitigation and adaptation, climate mitigation options in terms of sustainability, and development and equity considerations. The latest 5th IPCC was released recently. This has an important bearing on the joint modeling effort of 26 teams, viz., Coupled Model Intercomparison Project, as researchers from various disciplines try to estimate climate sensitivity of doubling of atmospheric carbon dioxide (CO_2) on the warming of the globe (Kerr, 2013; Kintisch, 2013). According to this report in Science (4th October 2013), although the sensitivity numbers have not changed since 1979 with a small margin of error, the model and data have advanced. However, 'the abstract quality of equilibrium sensitivity' is mentioned. The robustness of 'transient climate response' and its practical policy relevance is emphasized as it usually matches the simulated range generated from the models. However, in order to have a policy impact, modelers' research is often driven by IPCC's policy question (4th October 2013).

Regarding the geographical scope and capture of global interactions, especially as globalization has transformed organization of socioeconomic activities crossing boundaries, the models have evolved to take into account global spillovers. As Verburg *et al.* (2006, p. 121) argued:

> Only few global models of land-use land cover change have been developed and those global model analyses are not typically aimed at investigating land-use/land cover change issues per se, but, land-use/cover change can play an important role in analyses of climate change, biodiversity loss, agricultural production or world markets.

IAMs are examples of such models developed in the late 1980s–early 1990s and used for IPCC assessment of GHG emissions and global warming. These are also sometimes used in the IFPRI and the United Nations Environment Program for issues related to food and agriculture. However, models capturing economy-wide linkages between sectors and representative agents at the national level need to extend the

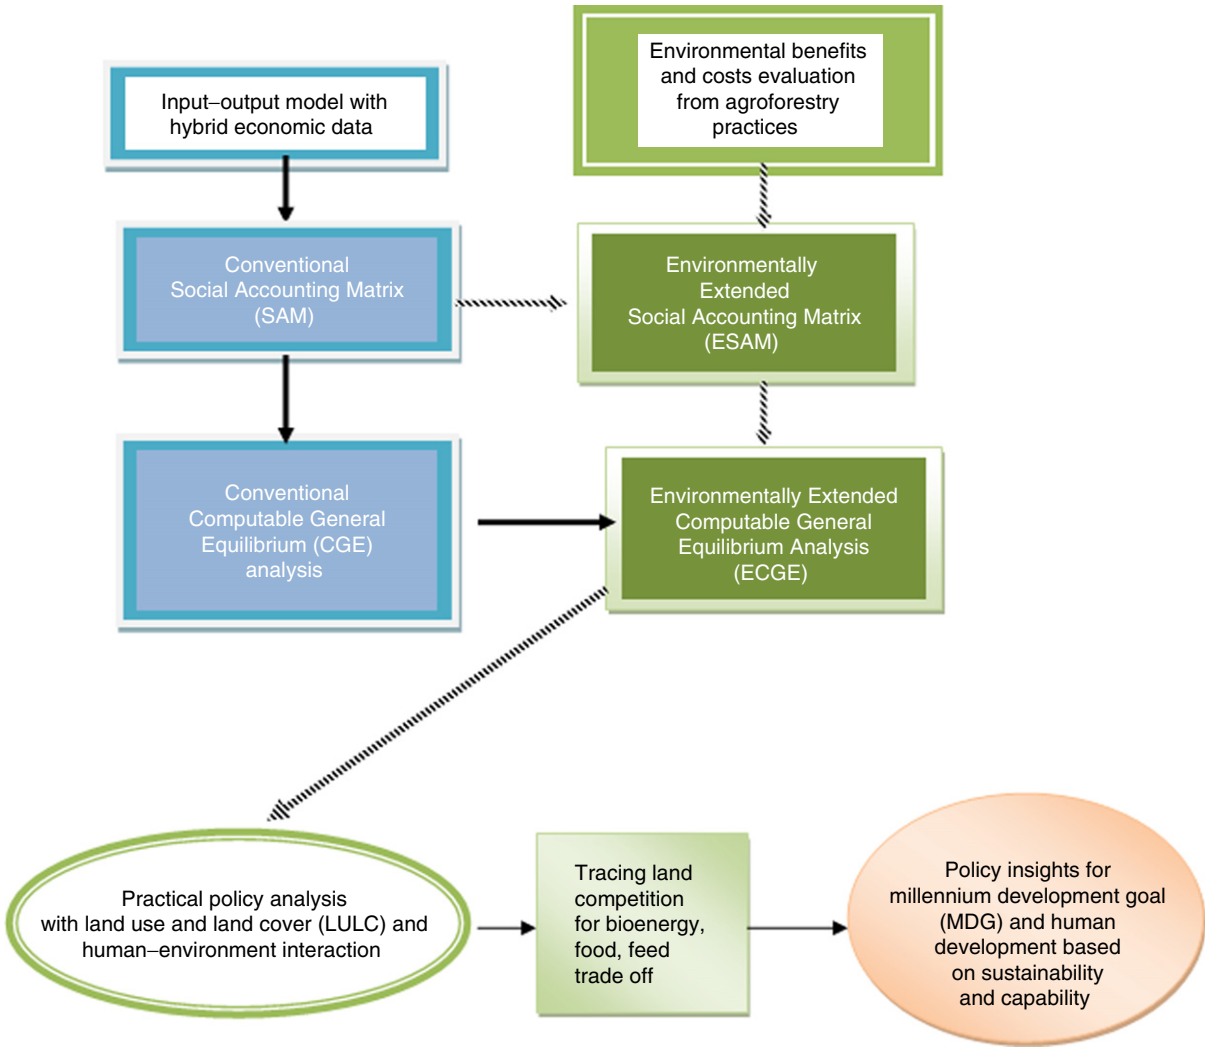

Figure 2 A stylized mechanism for environment–ecology–economy nexus and socioeconomic impacts.

framework to trace global impact, as many activities are not just confined to domestic boundary, rather they extend to global territory and causes climate spillover effects. Economy-wide economic effects of the policy changes are important as it generates spillover effects within the system. Hence, the CGE framework explicitly models the multisectoral linkage based on input–output models and the Social Accounting Matrix (SAM) and also focuses on goods and factor market interactions. Secondary impacts of development policy are assessed via the application of traditional input–output models (Leontief, 1986) with intersectoral transactions and different sets of multiplier effects. These are useful means of conducting the impact analysis. For modeling intersectoral transaction, Input–Output Models and SAM framework are used. SAM-based models are much detailed in the sense that in addition to intermediate input flows, they have a detailed institutional structure.

This kind of structure highlights on: (1) growing environmental concerns and preferences for biodiversity; (2) implications for socioeconomic benefits, equity, and distribution within income groups and environmental sustainability, (3) need for integration of Ecological, Environmental Benefits, and benefits with socioeconomic factors in an integrated approach for sustainable development, and (4) economic ecological nexus in an integrated framework. Figure 2 presents a mixed approach for ecological variable-augmented CGE framework.

The CGE models are equilibrium models where land allocation is done by demand–supply interactions of the land-intensive sectors. The GTAP is such a global economy model (Hertel, 1997) where land is immobile across globe; however, under the perfect competition assumption of factor and good markets, land is allocated as per its relative economic return in various uses. (In 1826, Von Thuenen gave a treatise on locational rent and his model for deforestation offers rationale for rent and perishability of goods to determine land use (Von Thuenen, 1826). There are also classical models that are not mentioned here, but they do not cover land-use information as detailed for lack of data.) In this macroeconomic model, with microeconomic foundations based on neoclassical optimization principles (e.g., utility maximization by household, profit maximization or cost minimization by the firms, and global savings being allocated to equate rate of return across

globe), heterogeneity of production processes across regions in the world and differences in global land-use patterns are not explicitly modeled.

In CGE models, the policy impacts on factor markets are studied, for example, trade policy impact on wage and factor returns and returns to land in case of agricultural policy shocks. In the context of the EU Common Agricultural Policy, the factor market project tries to predict the policy impact on agricultural factor markets, viz., for land, labor, and capital, which are not integrated like the food and agricultural markets. Banse *et al.* (2013a,b) studied such an aspect of factor market in MAGNET. This model is useful for studying the impacts of biofuel policies like Renewable Energy Directives and the United Nations Reduce Emissions from Deforestation and Degradation (REDD) programs, which cause change in land-use by limiting the land for agricultural and biofuel production and protecting and managing forest sinks and carbon sequestration. In particular, they studied this using GTAP Version 6 database with base year updated to 2010, and 45 regions and 26 sectors. Their headline results are, according to them (Banse *et al.*, 2013a,b, p. 41),

> …economic and population growth, together with biofuel policies, increases the demand for agricultural products and agricultural land use. The increased demand for land is met by increased yields and the conversion of forests and woodlands. The introduction of a REDD policy to protect forests and woodlands, limits the supply of land (6%) suitable for agricultural production, leading to the intensification of production and higher land prices.

As they find, for tropical regions this causes a rise in food prices and affects food security and vulnerability.

The economy-wide modeling has merits for public decision making as it enables simulation-based scenario analysis for ensuing policy changes and hence examining coherence of policy criteria. Thus, it provides a scientific understanding on the basis of judgments on social welfare and cost benefits. Hertel *et al.* (2013) had documented recent advances in the methodology of integrating LU in CGE models and incorporating a database of land use for agriculture, forestry, and biofuel policy mandates. This breaks ground in model development and is a reference work for work in the global land-use and climate change policy 'by offering a synthesis and evaluation of a variety of different approaches to this challenging field of research (Hertel *et al.*, 2013).' As Hertel *et al.* (2013) mentioned, development of such models is hindered by nonavailability of data on global land resource, non-CO_2 GHG and GHG emissions based on production activity, and sequestration drivers. These models take into account opportunity costs of land uses, trade-offs between agriculture and forestry, and the mitigation strategies. According to them, the FARM model by Darwin *et al.* (1995, 1996), which has disaggregated land resources into six heterogeneous classes based on length of growing period, offers rich ecological information based on spatial bioclimatic model. That was the first global CGE model with disaggregated land use information. Dynamic timber supply Model of Sohngen and Mendelsohn (1998) includes forest dynamics and incorporates the adaptive behavior of forest producers as well as the modeling of harvests and forest stocks. Other models are GTAP-AEZ model (Hertel *et al.*, 2013) with more extensive land-use database, forest carbon sequestration, and GHG emissions and GTAP-E and GTAP-L (Burniaux, 2002; Burniaux and Truong, 2002), which extend the static GTAP model by incorporating detailed features on energy production, demand, and substitution, for implementing Kyoto Protocol. It has interfuel substitution and a development of the underlying SAM to account for carbon tax revenues and expenditures, with a particular mechanism for trade in CO_2 emissions trading. As technological changes and productivity growth affects land use (e.g., biotechnology or bionanotechnology), this needs to be modeled. Das (2003, 2007) considered the impact of technological changes, especially information technology, forestry biotechnology in a comparative static and dynamic framework of GTAP-based augmented model to show the productivity gains and its benefits in terms of output and price affecting welfare. Das *et al.* (2005) simulated different forest conservation policies and spotted owl conservation in a multiregional applied general equilibrium model of the US economy. The Millenium Ecosystem Assessment (2005) has reiterated the growing interest in model building for researching land use-related effects and induced further effort in development of such joint modeling efforts. MEA shows the negative impact on crop yields due to adverse effects of environmental degradation as marginal productivity gains of technological progress decline. Different other models such as GTAP-AEZ (Hertel *et al.*, 2013), LEI Institute Trade Analysis Project, Kleines Land Use Model, etc. are briefly reviewed in Hertel *et al.* (2013). Baldos and Hertel (2012) developed a Simplified International Model of agricultural Prices, Land use, and the Environment in a partial equilibrium setup. This model – developed for better understanding of drivers changing global farm and food system and affecting agricultural land use, production prices, GHG emissions, and food demand – is used to simulate long-run changes of global farm and food system for historical validation for 1961–2006. This model is useful, as discussed in Section Land Use, Land Cover: Reconciliation of Issues and Evidences, for studying the impact of land competition for food demand and demand for land, thanks to ecosystem services, such as feedstock use by global biofuel/bioenergy demand.

Another genre of models is developed in a G-Cubed framework of dynamic nature. One of the important concerns in this technology-driven, high-growth world is about environmental sustainability. Many researchers have discussed the importance of addressing the climate change mitigation policies and the failure of Kyoto protocol so as to 'design a more durable post-2012 international agreement' or coordinated action (McKibbin and Wilcoxen (2008), to mention a few). This all depends not only on economics but also on national legal, accounting, and socioinstitutional structure in conjunction with international cooperation with a significant role being ascribed to economic theory as 'good guidance' for designing 'politically realistic policy' based on hybrid approach of multidisciplinary nature (McKibbin and Wilcoxen, 2002).

According to Stern (2007), aside from emissions trading and reduction of deforestation, technological cooperation, low-carbon technology invention, and investment in energy R&D are crucial. Analyzing impact of technological advances via biotechnology, ICT, and environmental technology on NRM, food security, and land use would be one of the major

focuses of the research. This would inform policy prescriptions to mitigate or facilitate adapting to global climate change initiatives. Analysis would address different policy designs, reduction incentives, conservation program, biodiversity issues, and climate and biofuel policies covering aspects such as broader impacts on the structure of (agricultural) production and interactions between climate and technology policies. Genetic engineering aided by IT development and combined with traditional practices produce sophisticated varieties adapted to local land and soil quality. In resource-poor nations, poverty, low productivity, and environmental degradation (deforestation and soil degradation) concatenate to cause a vicious spiral (see Das (2003, 2007)) in static and dynamic GTAP model).

Concluding Observations

This article has offered a broad view of the plethora of issues related to LULC and entangled with it the food–energy–environment trilemma. Climate change has been called a 'wicked problem' by Batie (2008). Climate change induces land-use change and vice versa. However, the changes are global and these worldwide changes cause repercussions to forests, cropland, waterways, and environment, and they are driven by the necessity to provide food–feed–shelter–bioenergy to almost 7 billion people. Challenges that are faced now involve trade-offs between human needs, economic prosperity, and managing global biosphere to maintain sustainably the capacity to provide burgeoning demand for goods and services in long run. The matter is complex and needs intensive research. The proposed analysis enlightened on the impacts of anticipated climate change on land use, agricultural production, food supply and availability, and other economic activities. This article is just a glimpse of the vast canopy of issues covering multidisciplinary perspective. As already seen, the issue crosses boundaries of natural science, social science, anthropology, and above all, the science for understanding the world as a complex adaptive system where land use and climate change should not be treated separately. As Sen (1995, p. 205) had stated: "The contemporary age is not short of terrible and nasty happenings, but the persistence of extensive hunger in a world of unprecedented prosperity is surely one of the worst.. However, food output must be one of the variables that can, inter alia, influence the prevalence of hunger." Further, Sen (1995, p. 209) argued: "Policy makers may be misled if insulated from the real situation of hunger – and even threats of famines – by favorable food output situations." Thus, the issue of land-use changes needs to be seen in broader perspective. Analytical models that capture these trade-offs could give some insight into the intricacies of such relationship. As Pindyck (2013, p. 870) had mentioned: "the physical mechanisms that determine climate sensitivity involve crucial feedback loops, and the parameter values that determine the strength of those feedback loops are largely unknown." These loops in the context of IAMs or complex models are important, as already seen in **Figures 1** and **2**, as 'feedback' is an inherent property of the human–environment interactive system. The tackling of the wicked problem needs a holistic approach.

Land Use: Management for Biodiversity and Conservation

SD Wratten, F Tomasetto, and DM Dinnis, Lincoln University, Lincoln, New Zealand

© 2014 Elsevier Inc. All rights reserved.

Glossary

Agroecology The science of understanding and enhancing the value of ecological processes in agriculture.
Conservation biological control (CBC) Enhancing the efficacy of biological control agents through habitat manipulation.
Ecosystem services Ecosystem functions provided by biodiversity that have value to humans.
Green revolution A system of enhancing crop yields through a combination of high inputs of water, fertilizers, and pesticides.
SNAP The four key resources that the natural enemies of pests need to increase for their ecological fitness and efficacy: shelter, nectar, alternative food, and pollen.

Introduction

"I am a photosynthesis manager and an ecosystem-service provider."
Peter Edlin, Swedish farmer

"Fuí por el mundo buscando la vida: pájaro a pájaro conocí la tierra"
"I've wandered the world in search of life:
bird by bird I came to know the earth"
Pablo Neruda, Chilean poet

The above quotations share and celebrate the vital importance of biodiversity for agriculture and human well-being. However, many people believe that agriculture is the greatest ecological experiment on Earth. Modern agriculture has high external costs and damages the natural environment. It is considered to be the biggest cause of climate change and is responsible for 24% of greenhouse gas emissions. Undoubtedly, modern food production is dependent on fossil fuels. In 2012, the International Energy Agency stated that no more than one-third of proven reserves of fossil fuels can be consumed before 2050 if the world is to limit climate change to 2 °C (IEA, 2012). Bearing this in mind, the Food and Agriculture Organization of the United Nations (FAO) showed that the current dependence of the food sector (including agriculture) on fossil fuels may limit its ability to meet future food demands. Recently, the University of Michigan, USA, has calculated that 10 cal. of fossil-fuel energy are used to produce 1 cal. of food energy on the plate (10:1). In 1940, the ratio was 1:2.3 whereas in 2000 it was 7.3:1 (Ahmed, 2013). Agriculture is in many ways in a state of tension; it minimizes and substitutes for processes, such as nitrogen fixation (substitute: urea), biological control (insecticides, herbicides, and fungicides), ecological succession (herbicides), soil formation and maintenance (exploiting action of soils), and plants' ecological traits matching ambient growing conditions, for example, water needs (irrigation) and food webs (one trophic level only).

Over the past century, as agricultural land use has intensified, ecosystems have been degraded and ecosystem services (ES) lost. In addition, biodiversity has been lost at a higher rate than during the last ice age. A consequence of biodiversity loss is reduced ES. In 1997, Costanza *et al.* estimated the value of global ES (based on a biome by biome approach) and suggested that the total ES value of the world was US$33 trillion. This figure was twice as high as the global gross domestic product (GDP) at the time. Although the article was criticized because of the many assumptions inherent in its value transfer approach, it did highlight the potential value of ES to the world. In the context of global agriculture, Costanza *et al.* (1997) ascribed a value of only US$92 ha^{-1} $year^{-1}$ for croplands. This is now considered to be a gross underestimate of the value of farm ES, as the economic value of earthworms alone well exceeds this figure.

International agencies are consistent in their view that modern, high-input, and substitution agriculture cannot meet the demands of a rapidly expanding world population, which is predicted to reach 9 billion in a few decades. Compounding that challenge is a current rapid global increase in meat consumption, especially chicken meat, which is largely driven by an increasing standard of living in parts of Asia. This is, in turn, driving a worldwide increase in demand for grain, which is likely to double in the next few decades.

A very relevant example of the threats to and opportunities for world food production is the report to the Human Rights Council of the United Nations in 2010 by Olivier De Schutter. He outlined agroecology as the key to ensuring the human right to food in a sustainable manner. Agroecology uses ecological principles to sustain and increase production while minimizing the impacts of substitution agriculture. Agricultural ecosystems based on agroecology are developed and managed by reinstating and enhancing natural processes, such as recycling nutrients and energy, integrating crops and livestock, and diversifying species, including noncrop ones. Internationally, agroecology is being seen as a way to improve the sustainability of food systems with several organizations now promoting its benefits, including the FAO (Food and Agriculture Organization of the United Nations, 2010); United Nations Environment Programme (UNEP, 2010); Intergovernmental Platform on Biodiversity and Ecosystem Services (IPBES, 2010) and Biodiversity International (2012).

A large-scale study, commissioned by the Foresight Global Food and Farming Futures project of the UK Government

 doi:10.1016/B978-0-444-52512-3.00082-6

(Pretty *et al.*, 2011), reviewed 40 projects in Africa that employed agroecology in the 2000s. The projects included crop improvement, integrated pest management, soil conservation, and agroforestry. By 2010, crop yields were doubled on average and 10.39 million farmers documented improvements in farming and food yields (Pretty *et al.*, 2011). In fact, De Schutter (2010) predicted that agroecology could double crop yields in developing and developed countries over the next decade.

Biodiversity, Agriculture, and Well-Being

How can biodiversity make agriculture more sustainable? Luck *et al.* (2003) argued that loss of biodiversity is commonly characterized by species extinctions. However, substantial changes to ecosystems and the status of biodiversity can occur through community structural effects before species extinction takes place. Luck *et al.* (2003) suggest a new approach to make the concept of ES and the deployment of ES enhancement more tangible and to promote end-user uptake. This was the idea of a service-providing unit. This essentially produces an ES enhancement 'recipe' to facilitate uptake by end users.

Well-being is now an area of interest, with researchers recognizing that appropriate exposure to green places and the right type of agriculture can improve well-being. Work by Barton and Pretty (2010) at the University of Essex, UK, has quantified the benefits to mankind of green exercise or a 'dose of nature' on self-esteem and mood. Examples of this effect can be seen among people using the UK's Public Footpath Scheme, where people who have access to farmland for walks have lower stress levels. In fact, exercise in green areas, such as farmland, beaches, forests, and nature reserves, and the consequences on well-being are the key components of current thinking on Genuine Progress Indicators (GPIs). Work by Costanza and others in this area has shown that GPIs have been declining since 1978 even though the more orthodox and flawed measure, GDP, has been steadily increasing over that time (Kubiszewski *et al.*, 2013). It follows that returning appropriate, functional biodiversity to agriculture can generate tangible benefits to humans as well as 'softening' the impact of modern farming on the environment and human health.

Case Studies: The US Prairies and the New Zealand Greening Waipara Project

Agroecological methods, such as conservation biological control (CBC), can increase the ES value of agriculture, while reducing its externalities caused by energy, pesticide, fertilizer, and fossil fuel use (Jonsson *et al.*, 2008). CBC enhances natural enemy efficacy through modifying the habitat – an approach easily remembered by the acronym SNAP (shelter, nectar, alternative prey, and pollen). The provision of flowering plants to enhance natural enemy fitness is a key aspect of CBC. Fiedler *et al.* (2008) conducted a review of current habitat management strategies involving all or part of SNAP and found that this management relied heavily on the four plant species, whereas plants native to the area and perennial plants were largely underrepresented. Here, the authors examine two case studies: habitat management in southern Michigan (USA) and native plants in New Zealand vineyards, both of which address this imbalance.

In 2003, studies were conducted in southern Michigan to use habitat management to help reduce pests by enhancing natural enemy effectiveness (Fiedler and Landis, 2007). Plant species that grew in declining prairies and oak savannas were investigated. They were added to this existing vineyard as plants under the vines. The study revealed that a modest number of native plant species can enhance the efficacy of natural enemies as well as 'nonnatives.' Feeding on floral resources alone will not automatically enhance pest control when using floral subsidies to increase natural enemy success. This must be measured against a hierarchy that includes the use of floral resource by adult parasitoids, the compatibility of the agent with the use of some pesticides, improved fitness of individual agents, and if the improved fitness applies to males and females. A decrease in pest populations, reducing growers' costs, and improved marketing opportunities complete the picture (Wratten *et al.*, 2003).

Vineyards are typically monocultures with a low provision of ES. However, the Greening Waipara Project, a government-funded initiative in New Zealand, is aiming to combat this problem (Bio-Protection Research Centre, 2010; Norton and Reid, 2013). In this study, the vineyard ecosystem was modified by the interrow planting of buckwheat (*Fagopyrum esculentum*; **Figure 1**), phacelia (*Phacelia tanacetifolia*; **Figure 2**), and alyssum (*Lobularia maritime*; **Figure 3**) to provide nectar

Figure 1 Flowering buckwheat in a vineyard interrow. Courtesy of Waipara Hills.

resources for key parasitoid wasps (Berndt and Wratten, 2005). The increase in parasitoid numbers that resulted from this work decreased the number of pests to below the economic injury level. In addition to pest control, other ES were developed, such as using New Zealand endemic plants as living mulch to disrupt the life cycle of *Botrytis cinerea* (a fungus that causes gray mold disease) or to suppress weeds.

Figure 2 Flowering phacelia in a vineyard interrow. Courtesy of Waipara Hills.

Habitat modification is not only pertinent to CBC, but it also plays a key role in other ES, such as attracting pollinators and enhancing their fitness (Wratten *et al.*, 2012). Gillespie and Wratten (2013) showed that, in both field and laboratory trials, the plant species *Veronica* 'Youngii' and buckwheat enhanced the fitness of butterflies, *Lycaena salustrius*, fitness more than other exotic plant species. If these floral resources are provided in vineyards and farmlands, then populations of butterflies may increase, contributing to their conservation.

The Urgent Need for Changes in Policy and Practice

Starting in the 1940s and reaching its peak in the late 1960s, the Green Revolution increased agricultural production around the world. The initiative was started by Norman Borlaug, the 'Father of the Green Revolution,' who has been credited for greatly reducing world hunger (Tilman *et al.*, 2001). Research and technology during this time transformed farming from subsistence to commercial operations. Mass production of crops involved the development of high-yielding cereal varieties, expansion of irrigation, creation of hybrid seeds, and a dependence on synthetic fertilizers and pesticides.

Although the Green Revolution increased food supplies, it had negative effects on food security, environment, and health. The latter was impacted by heavy use of agrochemicals. Increased food production does not mean better food security,

Figure 3 Strips of flowering alyssum in an organic lettuce crop in California. Courtesy of Mission Organics.

and critics of the Green Revolution argue that it does not take into account natural occurrences, such as historical famines and the socioeconomic or political situations in developing countries. The negative impact on the environment is largely undisputed; from pesticide and fertilizer pollution to the loss of agricultural biodiversity as a result of monocropping. There is conflicting evidence on the long-term health impact of pesticide consumption by humans. However, pesticide poisoning through the use of improper safety equipment and techniques is well documented. The Punjab region has been strongly affected by water contaminated with pesticides. Studies show that groundwater in its cotton region is contaminated with low levels of applied pesticides; with carbofuran and monocrotophos almost reaching maximum contamination levels (Tariq *et al.*, 2004). Additionally, water use in the Punjab region has caused the water table to decrease by 1 m $year^{-1}$ and 90 of 138 blocks in the state have declared extreme water shortages (Singh, 2004). Critics of the Green Revolution all address one common end point: current techniques are unsustainable.

In response to criticisms of the Green Revolution practices, a new type of farming initiative called the Evergreen Revolution was founded, led by the Indian Prime Minister Manmohan Singh (Swaminathan, 2000; Wratten *et al.*, 2013). This initiative was triggered in response to the conditions in India, where there are problems with malnourishment (International Food Policy Research Institute, 2012), and one of the more famous cases of negative health implications from pesticides is in Punjab (Ejaz *et al.*, 2004). With support from the US President Barack Obama, the United States and India entered into an agreement to develop, test, and extend food security, and form the partnership for an Evergreen Revolution (Office of the Press Secretary, 2010). This partnership means cooperation between Indian and American researchers and scientists to investigate and improve technologies to extend food security in India, Africa, and around the world (USAID, 2013). This approach is eminently appropriate for developing and 'developed' countries, as pointed out by De Schutter (2010).

To further develop world food security at a time when sustainable intensification of agriculture is increasingly being demanded, the relatively new science of ecological engineering needs to be widely adopted (Gurr *et al.*, 2004). This approach identifies, quantifies, and enhances farmland ES. This range of methods still remains largely unexploited despite a large number of prominent and sustainable successes. For example, insects that deliver biological control of pests do not operate well in agricultural monocultures and need resources supplementary to those provided by their prey. In vineyards in New Zealand, Australia, and elsewhere, the annual flowering plant buckwheat is regularly deployed in early summer between the vine rows to provide SNAP. The attack rate and longevity of a parasitic wasp within those vineyards are markedly enhanced by the nectar from buckwheat, leading to longevity of approximately 40 days compared with 3–4 days with water as a control. This leads to the numbers of a caterpillar pest within the grape bunches declining to such an extent that they fall below the accepted economic injury level. This means that insecticides are no longer needed, saving NZ \$250 ha^{-1} $year^{-1}$.

Recent unpublished work by H. Sandhu and S. Wratten in New Zealand evaluated ES provided by mineralization of soil nutrients and biological control of soil–surface pest eggs in organic and conventional arable farmland. When the economic value of these two ES for the organic farms was calculated and extrapolated to the area of arable land in the European Union, the resulting potential economic benefit for that region exceeded the total annual value of European farm subsidies. This profound result shows clearly that some new thinking is required for the policymakers to achieve true future farming based on a sound knowledge of how to evaluate and enhance farmland ES (Wratten *et al.*, 2013). The key challenge is to develop appropriate policy changes, including paying for ES and enhancing farmer uptake of agroecological protocols. The latter requires a keen recognition of social learning through which farmers most readily acquire new knowledge (Warner, 2007). The work of Keith Warner at Santa Clara University, California, is key to work in this area.

Glossary

Biodiversity A contracted form of 'biological diversity' and referring to the genetic, species and ecosystem levels of life in a specified region or globally.

Ecosystem function Processes such as nutrient cycling and energy flow that are key to the viability and sustainability of ecosystems. When ecosystem functions are directly exploited by humans – for example, in the form of soil formation, pollination and pest suppression – they are recognised as ecosystem services and can be assigned a value.

Reallocation Action to bring about a change to a degraded area of habitat to a new use or state from the original state of biological complexity and ecosystem function after a natural or human-mediated perturbation such as tsunami or pollution event.

Rehabilitation Action to bring about the partial return of a degraded area of habitat to its original state of biological complexity and ecosystem function after a natural or human-mediated perturbation such as tsunami or pollution event.

Restoration Action to bring about the complete return of a degraded area of habitat to its original state of biological complexity and ecosystem function after a natural or human-mediated perturbation such as tsunami or pollution event.

Introduction

Nuclear accidents, oil spills, and tsunamis have in recent times dominated the world's headlines. These events produce sudden and dramatic ecological degradation over a restricted area. Other changes such as pollution, soil degradation, desertification, or deforestation occur chronically over large sections of each continent. Where catastrophic events occur, their major impact on biodiversity occurs instantaneously, even though the residual effects may last for several years. In contrast, the impacts of long-term ecosystem degradation may occur over a much longer time scale as individual species become threatened and eventually become extinct. Ecosystem degradation is often a result of the expansion of intensive agriculture in many parts of the world (Rey Benayas and Bullock, 2012). Human development has frequently changed ecosystems which has lead to a reduction in biodiversity, ecosystem functions, and agricultural outputs. Reversing the effect of degraded agricultural land is important to improve agricultural output and so reduce the pressure on remaining native ecosystems (Dobson *et al.*, 1997). Ecosystem degradation can be addressed by restoration efforts if undertaken before substantial losses of biodiversity have occurred (Dobson *et al.*, 1997). If ecosystem degradation has not progressed too far, a return to an original state is possible simply by removing anthropogenic stresses and allowing natural processes to operate. This is not possible when thresholds of irreversibility have been passed. When such a threshold, which may not always be easily detected or quantified, has been passed, the system cannot be restored without intervention to correct the specific changes that led to the threshold being crossed (Aronson *et al.*, 1993).

Restoration

The term restoration is often used synonymously with rehabilitation. In most situations, however, to restore implies that an area of habitat will be returned to its original state with all biodiversity and ecosystem function reinstated to the predegradation condition (Law, 1984; Bradshaw, 1988; EPA: Environmental Protection Agency, 1995; Bainbridge, 2007; Rey Benayas and Bullock, 2012). One view of ecological restoration is that the goal is to create "a living museum in which flora and fauna are put back as they once were, seeking a complete or near-complete return of a site to a preexisting state" (Aronson *et al.*, 1993) (**Figure 1**). The term is widely used in relation to climax ecological communities such as forests and certain freshwater systems. These often have economic or esthetic value which serve as the drivers for restoration. Further, because climax communities represent an end-point for ecological succession, nearby areas of undisturbed habitat may serve as a benchmark for exactly what is to be sought in the restoration program. The natural processes of ecological succession may be used in the restoration process, for example, a gradual change from shrubby to long-lived woody vegetation with associated changes in faunal components such as birdlife. Accordingly, restoration activity may be passive in nature; sought simply by removing or ameliorating the factors that led to the original degradation. For example, control of feral grazing animals or allowing a natural wild fire regime may allow the return of native plant species which may then support the reestablishment of native fauna. More commonly, however, such passive actions are complemented by active efforts to speed up the process or to make step changes that otherwise may not occur because of the operation of a threshold for irreversibility. An example of such a step change is the reintroduction of an original plant or animal species that otherwise would not be able to reach the new area because of geographical isolation. Other active restoration actions include implementing biological control of a weed, reintroducing natural woody debris into streams to serve as fish habitat, and earthworks to stabilize regolith and reduce erosion.

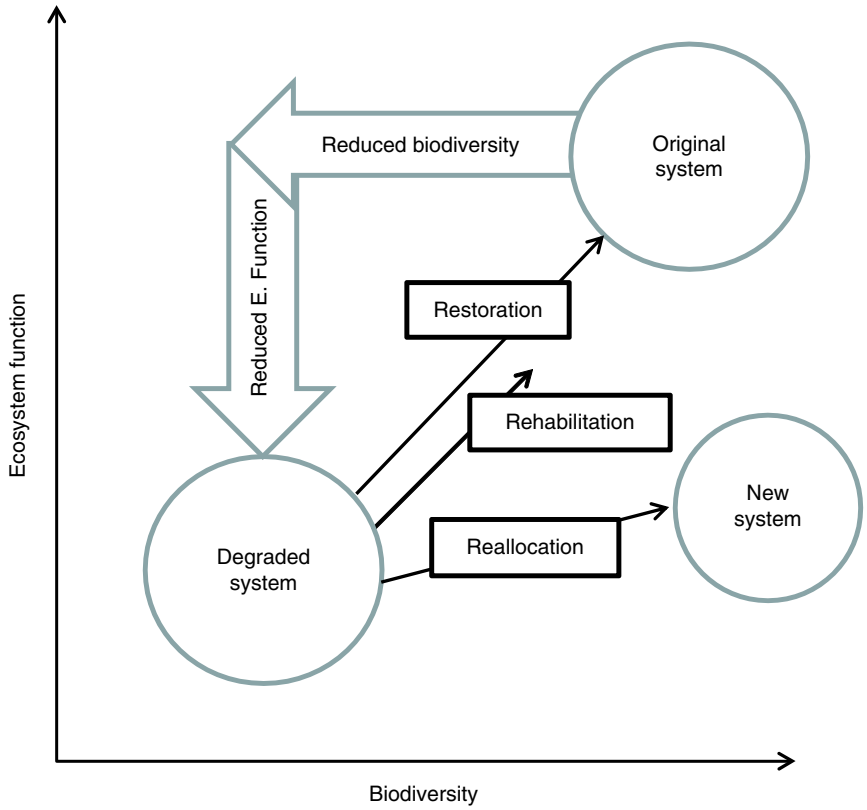

Figure 1 Degraded systems differ from the original state in typically having a lower level of biodiversity at the genetic, species, and community level and an associated lower level of ecosystem function. Restoration brings about a return to the original system, rehabilitation is a partial return to the original, whereas reallocation (or replacement) is a change to a third state. Adapted from Lugo, A.E., 1988. The future of the forest. Environment 30, 41–45.

In practice, restoration is difficult, expensive and slow; even when active restoration methods are implemented. This is because precise, ecological information on the goal of the restoration process may be lacking. Although restoring a patch of climax forest may be tractable when surrounded by undisturbed patches, a more common scenario is for the forest to be isolated and often remote from exemplar patches so information on key aspects such as the tree species and community composition have to be determined by extrapolation. Related to this, availability to the restoration project of biological propagules and founders is commonly a problem. Often the population density of original species in the degraded area is very low or nonexistent, even in more durable forms such as the soil seed bank. Any nearby habitat known to be similar to the original state of the restoration site may be able to donate seeds, tubers, and organisms. Otherwise, biological material from further afield needs to be obtained, introducing differences in provenance, a still greater issue when the taxonomy of species is poorly known as is common outside of North America and Western Europe. For invertebrates and microbes particularly, the poor state of taxonomic knowledge coupled with often high levels of endemism to small sites can be an important limitation of achieving full restoration to the original state. This lack of ecological information of historic or prehistoric ecosystems restricts restoration efforts as the goal is often ambiguous (Aronson *et al.*, 1993). A further major problem with restoration is that removal of species that have become established in degraded sites, such as weeds and small mammals, can be challenging. Many such species are reselected so have high powers of dispersal to new micro sites, are highly fecund so produce many offspring and rapidly reproduce after attempted control efforts, and may be invasive species that are freed from their natural enemies so lack important biotic regulators.

Complete restoration may also be inconsistent with society's current needs and values, this combined with the difficulties outlined above means that complete restoration of an ecosystem is often unachievable. The original ecosystem has taken centuries or millennia to develop so would be impossible to replicate faithfully (Bradshaw, 1988). Accordingly, many management efforts either aim for rehabilitation or reallocation, or are forced to settle for these outcomes when efforts to achieve restoration fail (Figure 1).

Rehabilitation

Rehabilitation is action intended to bring about the partial return of a degraded area of habitat to its original state of biological complexity and ecosystem function (Figure 1). This may occur after a natural or human-mediated perturbation such as a tsunami or pollution event. Essentially, many of the practices and challenges described for restoration apply also to rehabilitation; the latter is, however, made more tractable by

the fact that full restoration of the original system is no longer the aim. Rather, rehabilitation aims to improve to some degree a degraded site by increasing biodiversity at the genetic, species, and community levels and thereby reestablishing associated ecosystem functions such as trophic interactions, water, and nutrient cycles. Thus, to rehabilitate an area is to aim for something which is similar but a little less than full restoration. The goals are determined by what society wants and needs, the level of degradation, and the economical, political, and social environment (Law, 1984).

The diversity of land degradation whether it is pollution, soil degradation, desertification, or deforestation across each continent means that the end-point for rehabilitation is greatly varied. Rehabilitation can simply repair a damaged or blocked part of the ecosystem, which will restore some ecosystem productivity for the benefit of society. Rehabilitation seeks rapid change. Rehabilitation is like restoration, as it uses the indigenous ecosystem's structure and functioning as much as they can be determined (Aronson *et al.*, 1993). Rehabilitation often attempts to jumpstart a new ecosystem by removing the cause of the degradation that led to threshold of irreversibility being passed. Restoration, however, is usually attempted where no threshold of irreversibility has been passed (Aronson *et al.*, 1993). Rehabilitation is aimed at producing a stable productive ecosystem that is consistent with society's values (Law, 1984) but often with introduced species and less ecological complexity than complete restoration.

Reallocation

Reallocation, also known as replacement, is said to occur when management efforts do not seek to reinstate to any degree the original state of the ecosystem's structure and functioning (**Figure 1**). Rather, the nature or use of the site is deliberately targeted in some other direction. For example, a former mining site that led to the severe degradation of a natural grassland may be reallocated to a new use such as plantation forestry. Often, reallocation aims to achieve new landforms and landuses for society's benefit even when restoration is possible. For example wetlands, recreational areas, urban development, or agriculture (EPA: Environmental Protection Agency, 1995).

Degradation, Rehabilitation, and Restoration in Agriculture

Degradation

Both new and traditional demands for agricultural outputs are putting intense pressure on scarce land resources. Agriculture competes for land and water with growing urban settlements and industrial zones. There is also an increasing demand for bio-fuels (Food and Agriculture Organization (FAO), 2012). Agriculture is a major user of land (30% earth's surface) and water (70% extracted freshwater) and it is important to manage the quantity and quality of those resources (FAO, 2012). Despite efforts to conserve and recycle natural resources, the agriculture sector generates waste and pollution that can negatively impact ecosystems. For instance, agriculture is the main source of nitrate and ammonia pollution in both ground and surface water. It is also a major contributor to the phosphate pollution of waterways and the release of powerful greenhouse gases (methane and nitrous oxide) into the atmosphere.

Land degradation in the context of agriculture is the loss of the ability of land to produce food, fiber, and fuel either temporarily or permanently, or to maintain its natural ecosystem function. Land degradation can be caused by the removal of surface vegetation with the resulting loss of organic matter, soil, and plant and animal species (Cribb, 2010). Degradation of agricultural land is a problem as degraded land yields less and so contributes to rising prices as well as to declining viability of rural communities, value chains, and ultimately even to conflict and refugee crises (Cribb, 2010). Degradation also reduces other ecosystem services such as clean water, carbon dioxide absorption, and timber production. Saline or acid soils or those heavily polluted with industrial wastes are toxic to most plants and animals and can result in freshwater degradation resulting inland and water that is unfit for growing food. Pollution can be the result of heavy metals in runoff or fallout from the air from factories, spills, and leaks from transport accidents, the overuse of agricultural pesticides and fertilizers or in highly populated areas the poor disposal of sewage (Cribb, 2010). Potentially, harmful substances can cause a variety of illnesses in humans if polluted land is used to produce food (Cribb, 2010).

Salinity can be natural but agricultural activities, chiefly irrigation and clearing of perennial vegetation, can lead to or exacerbate salinity to the extent that this form of degradation now affects about a tenth of the earth's land surface (**Figure 2**).

Figure 2 Farm rehabilitation seeking to deal with soil salinity in Australia. Regenerating trees on the distant rise and saplings sown in fenced-off areas in middle distance access and use water, preventing recharge of the water table while perennial pasture species are used in place of annual species in the low lying foreground. Piezometers (white plastic tube) allows monitoring of the water table height and periodic measurement of electrical conductivity.

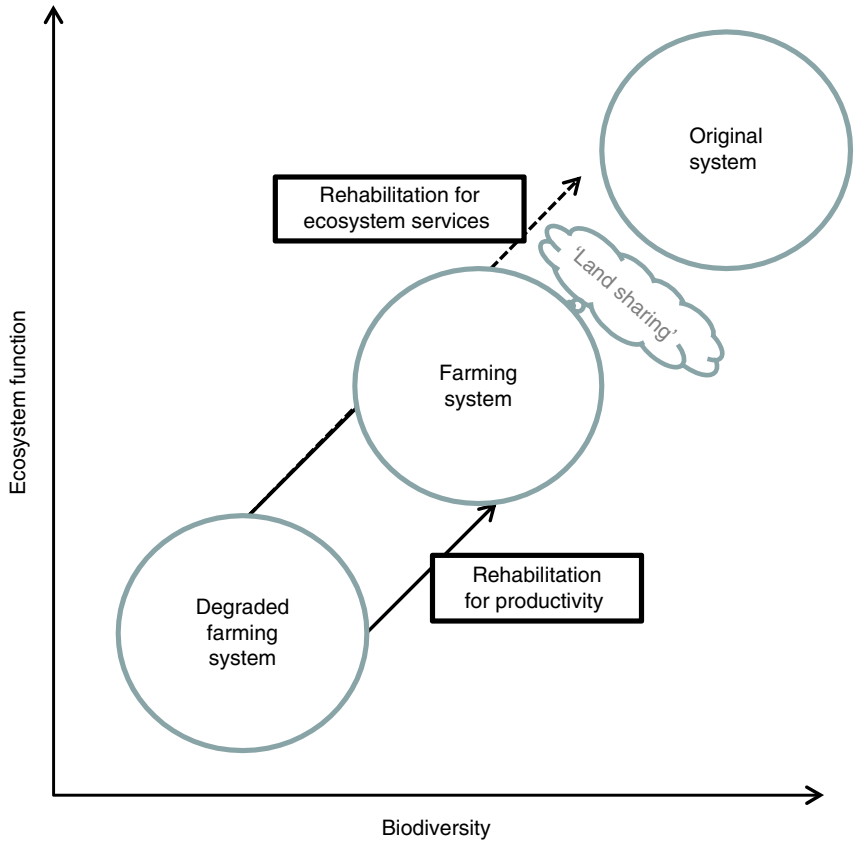

Figure 3 Farming systems are degraded natural systems with lower levels of ecosystem function and biodiversity. They are vulnerable to further degradation that frequently requires rehabilitation efforts to maintain farm productivity. Increasingly, agricultural rehabilitation goes further such that natural biodiversity and farming share the same area with agriculture benefitting from enhanced ecosystem function.

Soil acidity is associated with agricultural activity because most agricultural products are slightly alkaline in their chemical composition so their repeated removal from a site leaves the soil increasingly acidic. For example, the removal of one ton of alfalfa hay requires the application of 70 kg of lime (calcium carbonate) to neutralize the resulting soil acidity. Acidity can also result from fertilizer use, particularly the nitrogenous fertilizers ammonium sulfate and monoammonium phosphate. Further, when nitrates are leached from the topsoil to below the root zone, or from the site entirely, this leaves the soil acidic.

Removing the protective cover to reduce competition for water and nutrients, plowing, heavy grazing and deforestation leave the soil highly vulnerable to wind erosion, particularly during severe droughts. Heavy grazing around water points or during long droughts prevents or delays the regrowth of vegetation or favors only invasive shrubs. This problem is particularly acute in parts of subSaharan Africa, where inherently low soil fertility, severe nutrient depletion, and poor soil structure are prevalent. Heavy fertilizer applications are unaffordable and too risky in these low-potential rain fed cropping systems.

Improving land and water management techniques can rehabilitate agricultural land and restore productivity. Conservation agriculture, improving soil fertility, integrated pest management and other agronomic techniques such as crop rotation can all contribute toward rehabilitating agricultural land (FAO, 2012).

Restoration and Rehabilitation

In the context of agriculture, the concepts of restoration and rehabilitation as used in natural ecosystems need to be tempered by the fact that agriculture is a human activity that has replaced natural systems. Accordingly, agricultural systems constitute habitats with degraded ecosystems in terms of biodiversity and ecosystem function in all respects other than the production of agricultural products (**Figure 3**). This is reflected in the fact that modern agricultural systems are heavily reliant on inputs of allochthonous water, fertilizers, and fossil fuels to generate high yields, and on pesticides and managed honey bees to replace natural pest regulation and pollination. Globally, however, agriculture is widely affected by forms of degradation described above that may be a direct result of the agricultural activity or by external factors such as seawater inundation and pollution. Together, these types of degradation mean that rehabilitation efforts are frequently practiced on farmlands. Most commonly, the aim of these efforts is to address the degradation to restore the site's capacity for productive agriculture. Increasingly, however, the aim may be to take a farming system to a state somewhat closer to the type of

habitat that was present before agriculture was practiced at the site (Figure 3).

Rehabilitation for Agricultural Productivity

Agriculture dominates terrestrial land use in most areas of the globe where the land is inherently suitable for production. This reflects the pressure imposed by the burgeoning human population, predicted to reach 9 billion by 2050. Coupled with rising living standards and attendant need for animal proteins, population growth will mean that the global demand for food will increase for at least another 40 years (Godfray *et al.*, 2010). The human population is likely to plateau at some 9 billion people by roughly the middle of this century. This momentous challenge to agricultural technology illustrates the pressure on farmlands to achieve ever greater levels of productivity, underlies why degradation is increasingly common in these stressed systems and illustrates the importance of successful rehabilitation.

In this context, rehabilitation projects aim to deal with forms of degradation such as soil erosion (Figure 2) to restore farm productivity. Soil degradation resulting in reduced yields is estimated to affect 16–40% of land area and is expected to expand (Tscharntke *et al.*, 2012). Some soil losses around the world are in excess of 50 ton per hectare in a year which is up to 100 times faster than the rate of soil formation (Banwart, 2011).

When considering a rehabilitation approach, it is important to understand how the degradation occurred as removal of the cause can be the start of the solution (Oma, 1992). As well as understanding the cause of the disturbance, the degree of degradation, the productivity goal and economics and timing will determine the methods used (Bainbridge, 2007). Rehabilitation practices range from land surface shaping and drainage management to soil amendments, minimum or zero tillage practices or weed removal or other agronomy practices. Rehabilitating ecosystem services could also include the reestablishment of a single taxon or specific function such as a pollinator or improved drainage.

The soil is central to many forms of degradation in agriculture so many rehabilitation efforts focus strongly on management of soil chemistry, structure, and biology. For example, nutrient deficiencies can be overcome in the short term by the application of artificial or organic fertilizers though care needs to be taken to avoid fertilizer forms and application patterns that lead to acidification. In the longer term, the introduction of nitrogen-fixing plant species, use of perennial crops, pastures and noncrop vegetation, and a return to mixed farming systems that integrate cropping and livestock can provide more durable solutions. Improving the structure of the soil can take a long time and depends on the soil type and the climate; however, biological properties can be reinstated within 10 years (Dobson *et al.*, 1997). A more difficult problem is the decontamination of soils polluted with heavy metals, radioactive materials, or certain organic compounds. Costly approaches such as mass removal or covering with new topsoil are suitable only for small areas. This has led to interest in the potential of phytoremediation, the use of plants to take-up the pollutants from the soil. The plants are then harvested and removed. Even factoring in the costs of these actions and disposal of the contaminated plant material, this strategy is less expensive than traditional approaches. Future advances in plant breeding and processing technology may even allow the pollutants to be recovered and reused.

Figure 4 An example of an agri-environmental scheme feature in southern Britain that constitutes rehabilitation of farmland toward the original habitat. A mixture of flowers sown and managed specifically to support pollinator insects such as bumble bees replaces crop land but earns the farmer payments from a government-funded stewardship scheme.

From Agriculture toward a Former State

Despite the pressure imposed by the burgeoning human population and its expanding demands, there is a recognized need to preserve biodiversity if only for purely selfish reasons of the ecosystem services provided (e.g., carbon sequestration from the atmosphere). Reflecting this, many countries have introduced land sharing schemes whereby agricultural and biodiversity uses are balanced on a given site. Such agri-environmental schemes are often encouraged by payments from the government to farmers, usually for specific land stewardship activities such as planting trees or maintaining grassy or herbaceous vegetation for wildlife or pollinators (Wade *et al.*, 2008). In this context, rehabilitation projects generally involve taking an area of land out of agricultural production; often this is a minimum proportion of the farm as prescribed under a legal framework. Then, passive management may be used, relying on the natural regeneration or establishment of desired plant species. A problem with this approach is that propagates of desirable plant species may be dramatically outnumbered by those of weedy species, particularly if the area has been under cultivation for a long period and is remote from natural vegetation remnants. If weeds are allowed to flourish in areas take out of production they can threaten the productivity of other parts of the farm and neighboring properties. For this reason, rehabilitation of farmland is usually more active and this may be a requirement of agri-environmental schemes that involve financial incentives. Active restoration is practiced by planting trees, hedgerows or sowing desired, native grassy and herbaceous species (Figure 4). Together, such management efforts go beyond attempts to restore the productivity of the

farmland and constitute rehabilitation toward the original nature of the area before agriculture was practiced (Figure 2).

Case Study: Posttsunami Rehabilitation of Farmland

On the 26th December 2004 an earthquake of magnitude 9.3 generated a tsunami in the Indian Ocean affected more than 12 countries causing extensive loss of life (230 000 people in 9 countries) and damage to properties along the coastal areas of these countries (Prih Harjadi, 2008). The tsunami had a severe impact on the local environment, and caused extensive damage to the coastal ecosystem (Shaw, 2008). Tsunami also caused a massive inflow of seawater over the coastal inland agricultural systems and severely affected soil and water resources. The earthquake caused a drop in elevation on some parts of the coastline causing agricultural land to be submerged (Slavich *et al.*, 2008). Areas previously suited to intensive agriculture deteriorated very rapidly because of seawater inundation and deposits of salty sediments (Chandrasekharan *et al.*, 2008; Slavich *et al.*, 2008). In some areas, permanent inundation has resulted in some losing their livelihoods (Niino, 2008; Shaw, 2008). The most saline soils are present where tsunami water lay for longest and these areas suffer the greatest crop yield losses. Shallow groundwater sources were also affected, rendering them unfit for irrigation and domestic use in places (Shaw, 2008; Slavich *et al.*, 2008).

Immediate rehabilitation efforts include the repair of agricultural infrastructure including irrigation channels, clearing of debris, scraping surface salt from fields, and the application of gypsum to selected fields (Niino, 2008). Aid was provided in the form of farm implements, fertilizer, or compost and distribution of salt tolerant crop varieties in the form of seed, seedlings, or cuttings (Niino, 2008).

It is important to reduce the effect of soil salinity on agricultural land by having effective drainage networks to allow seawater to drain from fields. Irrigation and drainage channels had to be cleared of debris and reshaped. In areas where this was not feasible it was estimated it would take years for the land to be rehabilitated. Good rainfalls in the year after the tsunami flushed and leached salts from soils where drainage was adequate such that soil electrical conductivity fell to levels that allowed for crop growth (Abubakar and Basri, 2008; Chandrasekharan *et al.*, 2008).

Reducing salt accumulation can be facilitated by adding soil ameliorants to improve enhance structural stability of the soils and correct nutrient imbalances. Ameliorants can include gypsum, organic matter such as green manure or compost (Abubakar and Basri, 2008). Initial rehabilitation efforts were focused on land with light or medium damage, within 3–4 years most of this land was rehabilitated and under cultivation and work had begun on more heavily damaged land which included the rebuilding of paddy fields (Abubakar and Basri, 2008).

Vegetable, cereal, and tree crops can be grown in tsunami affected soils by selecting species and varieties that tolerate soil salinity. There are rice cultivars and tree crops that are tolerant of salinity and able to be planted in tsunami affected soils. Some of these are regularly grown in tidal swamp areas. (Chandra Mohan, 2008; Joshi, 2008).

Longer-term strategies include new investment in agricultural field drainage technologies, provision of water harvesting structures, and the desilting of drainage channels and watercourses (Chandrasekharan *et al.*, 2008). Further, unsustainable land use expansion combined with demographic growth into marginal areas are responsible for elevating the level of exposed to natural risks and increased the region's vulnerability to environmental impacts that extreme natural events, such as tsunamis, may cause (Shaw, 2008). Accordingly, responses should be directed toward the prevention and mitigation of the environmental impact of natural disasters as well as to the rehabilitation and reconstruction of sites damaged by such events. The capacity of a region to resist or ameliorate the impact of a disaster is related to the provision of environmental services based on the natural resources available in that region such as well preserved ecosystems (Shaw, 2008). Areas of mangroves in coastal zones (Hogarth, 2001) are one relevant example.

Earlier natural disasters such as volcanic eruptions have led to the short- or long-term abandonment of agricultural land and it was ultimately the overall economic and social 'health' of the farming system that determined the level and speed of recovery (Wilson *et al.*, 2011). Natural disasters may act as a catalyst, accelerating the rate at which adjustments in ongoing economic and social systems occur. Community resilience is largely dependent on preexisting social, economic, and political conditions as well as postdisaster responses, relief effort, mitigation strategies, and longer-term rehabilitation programs (Wilson *et al.*, 2011). A well-planned rehabilitation program will take the opportunity to improve agriculture such as introducing higher yielding crops and/or varieties and improving existing infrastructure and support systems (Chung, 1987). Responses from donor countries and international agencies with relief assistance are often immediate but agricultural rehabilitation, because of its long-term nature and high cost require ongoing efforts by the governments and communities of the affected countries (Chung, 1987). Many nongovernment organizations (NGOs) promote the idea of 'build back better,' for example, restoring natural ecosystems such as mangroves. Some such work has, however, been considered wasteful as it was implemented in some cases without proper postdisaster surveying (Cochard *et al.*, 2008). NGOs have also paid locals to implement natural ecosystems restoration schemes but this creates a false economy and can result in exacerbation of farm abandonment as rural workers prefer cash employment (Cochard *et al.*, 2008).

The Future of Rehabilitation in Farmlands

Many ecosystems have been transformed or degraded by human use, and restoration offers an opportunity to recover services and benefits as well as less tangible benefits such as aesthetic and recreational value (Aronson *et al.*, 2010). In farmland, ecological restoration can contribute to sustainable agriculture by directly addressing many forms of degradation whether caused by agricultural activities or by external perturbations. Increasingly, rehabilitation efforts undertaken in farmlands go further. Agri-environmental schemes in many parts of the world move degraded agroecosystems closer to

their original, preagricultural state thereby restoring significant amounts of biodiversity and associated ecosystem services (Wade *et al.*, 2008). Agroforestry represents an intermediate step between natural secondary forests and reclamation of severely degraded land in terms of high versus low provision of biodiversity and ecosystem services, state of degradation, and time and costs of forest restoration. Agro-successional restoration schemes have been proposed, which include agro-ecological and agro-forestry techniques as a step before forest restoration (Rey Benayas *et al.*, 2009).

Farmers are increasingly aware of the ecosystem services performed by agricultural biodiversity. These include pest suppression, conservation of pollinator species and wildlife, fixation of atmospheric nitrogen, nutrient cycling. Strategies for enhancing these are many and varied but adoption tends to be strongest when the right forms of diversity are selected and incorporated into farming systems with the minimum of disruption to normal farming practices (Gurr *et al.*, 2004). Examples of farming practices and landscape features that favor biodiversity include strategic revegetation of property boundaries, field margins, and track edges to create living fences, planting isolated trees to take advantage of their disproportionate positive value of biodiversity conservation and potential for seed dispersal, creation of pollinator friendly areas using specific plants and nesting habitat, the introduction of overwintering habitat, and nectar plants for natural enemies of pests (Rey Benayas *et al.*, 2009). An important current example is ecological engineering of Asian rice. Planthopper pests have devastated rice crops throughout Asia over the past 5 years, largely because of the overuse of insecticides which have reduced the diversity of natural enemies and led to the development of insecticide resistance in pest populations. Further, the widespread use of a relatively small range of rice varieties has meant that planthoppers have also evolved immunity to the traits in rice plants that previously conferred high levels of insect resistance. This erosion in efficacy of the two mainstays of pest control (insecticides and pest-resistant varieties) necessitated action to reinstate natural mortality of planthoppers imposed by a wide diversity of predatory and parasitic arthropods. A range of plant species was evaluated in laboratory experiments and led to the identification of sesame as one suitable for boosting the longevity, fecundity, and impact of parasitic wasps and predators. This was then promoted for use on the earthen banks around rice fields where it gave good control of pests (**Figure 5(a)**). This rehabilitation strategy has become widely used in China and Vietnam because it gives farmers a highly tractable method to rehabilitate their farms to a state similar to that of traditional rice production landscapes such as of Sanmen in eastern China, where rice is produced in mixed farming systems without the need for insecticides (**Figure 5(b)**).

In alignment with the value of biodiversity to agricultural production through greater operation of ecological goods and services and less reliance on synthetic inputs, the fact that 40% of terrestrial area is under agricultural management and just 12% is protected means that the protection of biodiversity requires a highly connected matrix made up of seminatural habitats, managed habitat including farmlands as well as reserves (Tscharntke *et al.*, 2012). Management of biodiversity, in habitats outside of farming systems can be used to benefit agricultural production and enhance ecosystems services (Rey Benayas *et al.*, 2009). This differs from any notion of a wholesale reversion to traditional agricultural methods which would reduce food production massively. Restoration and rehabilitation efforts to benefit wildlife and ecosystem services to agriculture can employ highly specific actions intended to benefit particular taxa or guilds and ecosystem services such as pollination and natural pest regulation. Relevant strategies often occupy only small fraction of the agricultural land, meaning that they compete to only a small degree with productive farmland use.

Some have found that the majority of plant biodiversity is found in small fragments of noncrop habitat suggesting that in ecosystems with little noncrop habitat, biodiversity can be improved by land sparing (Egan and Mortensen, 2012) where agricultural land is farmed intensively and remaining natural habitat is protected. According to Phalan *et al.* (2011), land sparing conserves biodiversity more effectively than land sharing where land is not protected but is managed in a wildlife-friendly manner. Many authors argue about land sparing, stating that it requires proper implementation and is not a system that can be transferred across different ecosystems

(a) (b)

Figure 5 (a) A rice crop in eastern China in which rehabilitation of natural pest control has been achieved by use of sesame on the bunds to provide nectar to enemies of pests, (b) a traditional rice production landscape in eastern China where the diversity of crop and noncrop vegetation allows production without the need for insecticides.

(Fischer *et al.*, 2011; Tscharntke *et al.*, 2012). Others also argue against land sparing approaches as agricultural intensification can result in increased land clearing or movement of agriculture into unsuitable areas and a high use of pesticides. Improved knowledge of biodiversity can lead to improvement in agricultural yields as well as improving biodiversity (Fischer *et al.*, 2011). Much of the food insecurity at present is caused not by insufficient agricultural production but by poverty and problems of socioeconomic access (Ratnadass *et al.*, 2012). Tscharntke *et al.* (2012) also argues that world food shortages are better resolved by less wastage and better distribution of the foods currently produced rather than increasing food production.

Although ecological restoration is challenging to achieve, rehabilitation is far more tractable and generally widely regarded as essential not only for conserving biodiversity, but also for promoting economic development and sustainable livelihoods, particularly in developing countries. Likewise, restoration within and around degraded ecosystems provides a powerful tool for increasing resilience and connectivity in natural environments, thereby reducing the vulnerability of these ecosystems and their resident biodiversity to the projected consequences of climate change (SER Society for Ecological Restoration, 2009).

Glossary

Basic economic sector Produces goods and services for consumption outside the local region (export consumption).

Cointegration A statistical property of time-series variables. Two or more time series are cointegrated if they share a common stochastic drift, such as stock market indices and the stocks that make up the indices.

Compensating variation The amount of money that just compensates a person, group, or whole economy, for the welfare effects of a change in the economy, thus providing a monetary measure of that change in welfare.

Consumer surplus The difference between the price a consumer pays for an item and the price he would be willing to pay rather than do without it.

Equivalent variation Measures the amount of money that, paid to a person, group, or whole economy, would make them as well off as before the specified change in the economy.

Kaldor–Hicks improvement Any alternative that increases the economic value of social resources. Kaldor–Hicks is related to Pareto efficiency. Under Pareto efficiency, an outcome is more efficient if at least one person is made better off and nobody is made worse off. Under Kaldor–Hicks efficiency, a more efficient outcome could leave some people worse off but an outcome is more efficient if those that are made better off could in theory compensate those that are made worse off and lead to a Pareto optimal outcome.

Nonbasic economic sector Serve the needs of the local basic sectors and local resident population or consumption.

Producer surplus Measures the difference between the amount that a producer of a good receives and the minimum amount that the producer would be willing to accept for that good.

Introduction

Rural America has realized rapid demographic and economic structural changes over the past several decades. By 2000, the last Census to report farm employment showed a decline from approximately 32.0 million in 1920 to approximately 3.0 million workers in 2000, its lowest value of all time (Dimitri *et al.*, 2005). Also from July 2011 to July 2012, nonmetropolitan population fell by 0.2%, which was the first ever decline in nonmetropolitan population recorded by the Census (USDA, 2013).

During this same period the structure of the nonmetropolitan nonfarm economy was also changing. Nonmetropolitan county economies have a strong resource base, and the proportionate share of farm sector employment in total nonmetropolitan employment declined from 14.4% in 1969 to 5.6% in 2011 (U.S. Department of Commerce, 2012). Although there is a perception even in nonmetropolitan counties that agriculture is the primary employment sector, by 2011 the manufacturing sector (10.0%), the retail sector (10.9%) and the health care and social assistance sector (10.0%) each had larger proportionate shares of total nonmetropolitan employment than agriculture (Goetz *et al.*, 2013).

It has also been suggested that even with economic structural change, the agricultural sector provides stability in many rural economies. As Moline *et al.* (1991) found in Wyoming, agricultural producers have fixed levels of operating expenditures that must be covered in a given year. Many agricultural sector expenditures involve purchases from local businesses and the fixed expenditure level provides some stability to the local economy. With lower output or higher input prices, most agricultural producers will realize lower returns while trying to maintain output levels and expenditures. Changes in production levels due to drought, rangeland fires, or government production reduction policies will impact the stability of these farm expenditures.

The overall structure of nonmetropolitan counties has been impacted not only by changing agricultural sector relationships in rural economies, but also by structural change in agriculture itself from greater vertical integration between producers, processors, and distributors. This vertical integration of agriculture or what has been characterized by Drabenstott (1995) as the 'broilerization of agriculture' produces a different linkage between agriculture and the rest of the rural economy. In fact, many states have targeted agriculture as a cluster industry but what they are really referring to is agribusiness as their economic target.

Given the changes in nonmetropolitan population and the restructuring of the agricultural sector, a number of state, and local studies have been commissioned to measure the contributions of the agricultural sector to the local, regional, or state economy. Leones *et al.* (1994) identified 14 states that completed contribution analyses of their state's agricultural industry. Of interest in all of these studies is how agriculture is defined. If the study extends beyond the farm gate, it becomes

 doi:10.1016/B978-0-444-52512-3.00124-8

an agribusiness study which can include agricultural manufacturing, distribution, and retail. In this case a serious problem of double counting can arise, if agricultural sector impacts are counted twice.

As discussed in Section Introduction, agriculture has the potential to have substantial ripple effects on rural economies from changes in activity. Changes in agricultural economic activity may occur in response to drought or disasters (weather or fire), expansion of foreign trade or location of agribusiness firms, adoption of new technologies, or changes in public policies. These changes are felt throughout most rural economies because of the agricultural sector's economic linkages within the local economy. Because of these economic linkages, government officials, business decision makers, and concerned citizens are profoundly interested in the total and distributional impacts of changes in agricultural activity in their local economy, and in order to shed light on these ripple effects or impacts, economic models are often employed. If these models are incorrectly used, the resulting analysis will be misused, disregarded, or discredited by the public. Poorly executed studies can actually cast a shadow of doubt on agriculture, which can work against the industry within the larger community.

The principal objective of economic impact modeling is to identify changes in the local, regional, or state economy from positive or negative changes of a particular segment of the economy (Davis *et al.*, 1999; Cummings and Morris, 1997; Goetz *et al.*, 2009). These studies are often based on either economic base or input–output (IO) models but more advanced models have been applied which include social accounting matrix (SAM) models, computable general equilibrium (CGE) models and conjoined econometric/inter-industry models. Here the authors discuss the use of impact models for analysis of changes in agricultural activity and the potential misuses of these models. This article is divided into two major sections. The first section discusses the alternative models that can be used to derive economy-wide impacts from changes in agricultural sector activity. The second section discusses the different metrics of economic impact modeling as well as the impacts of the size of the study area. Social and public sector impacts can and should also be incorporated in a detailed analysis but are not addressed here. For social and public sector impacts early studies from the Western Rural Development Center provide excellent information (Weber and Goldman, 1979; Faas, 1980; Siegler and Meyer, 1980; Cooke *et al.*, 1996).

Models for Estimation of Impacts

Economic impact models' primary objectives are to derive overall and distributional impacts in the local, county, state, or national economy from positive or negative changes in a particular segment of the economy, such as agriculture (Davis, 1990; Cummings *et al.*, 1998). Impact studies, especially those investigating the distributional impacts of changes in agricultural sector activity have been either export/economic base, IO, SAM, conjoined econometric/IO models, or CGE models. The authors next review these in turn.

Economic Base Models

Export- or economic base models have a long history dating back to the 1940s. North (1959) pointed out that export sales, including agricultural exports, led to US growth from the 16th to 19th centuries. The premise of export/base economic models is fairly simple: to promote economic growth at the local level one must increase exports out of the region which in turn injects money into the region. Historically, this has caused policy makers to focus on goods-producing industries, such as agriculture, mining, forestry, and manufacturing as the 'engines of economic growth.' More recently, Kilkenny and Partridge (2009) questioned the reliance on export-base growth models for contemporary rural growth initiatives. For example, over the past 50 years the economy has moved from a goods-producing economy, a focal point of export-base analysis, to a services-producing economy. Export- or economic base models also have been criticized because of their theoretical weaknesses by Krikelas (1991) and Isserman (1980) (e.g., all regions export and none import).

Export- or economic base models are thus not without criticism or problems in their use or calculation. These criticisms or problems are (1) the identification or measurement of sector basic and nonbasic employment or income, (2) an oversimplified theory, (3) stability of multipliers over time (Brown *et al.*, 1992; Gerking and Isserman, 1981; Stabler and Howe, 1988; Williams, 1996).

Identification of economic base

The first criticism of base multipliers is the bifurcation of sectoral employment into basic (exporting) and nonbasic (nonexporting) employment or income. Sectoral employment and income are not reported separately as basic or nonbasic values, and therefore empirical procedures must be used to bifurcate the data into its two components. Four procedures have been suggested to bifurcate the data which are direct interviews, assumption procedure, location quotients (LQs), and minimum requirements.

The direct methods procedure employs surveys of local businesses and households to bifurcate the flow of local economic activity (Tiebolt, 1962). Interviewing local businesses and households, however, is expensive and time consuming. Also, with any interviews the representativeness of the sample may be questioned and the accuracy of replies by businesses and households as to proportions of total business activity or household consumption that are exported may be questionable.

To address problems of timeliness and expense, indirect procedures have been developed to bifurcate sectoral employment or income. One indirect method is the assignment procedure. For this indirect method, the researcher or focus group assume or agree on the proportion of total sectoral activity that represents exports. This procedure has no theoretical backing and depends on the researcher's or focus group's knowledge of the local economic sector. It is sometimes referred to as the 'expert assignment approach.'

Another indirect procedure to bifurcate sectoral employment or income is the LQ approach. This procedure's premise is that the more specialized a given region's sector, for example, agriculture, relative to total regional activity, the more

of the sector's economic output is exported. A LQ for a given sector i in a region r is estimated as:

$$\mathrm{LQ}\,i,r = \frac{\text{Percentage of total regional } (r) \text{ employment in sector } (i)}{\text{Percentage of total national employment in sector } (i)} \quad [1]$$

If the percent of employment or income in sector i, such as agriculture, in region r is greater than the percentage of agriculture in the nation, then part of that sector's employment or income is made up of exports. If the sector's proportionate share of total employment is less than the national share, however, the sector's employment or income is classified as nonbasic.

Minimum requirements are another indirect method to derive a sector's and region's export base or basic employment or income. The main difference between the LQ and minimum requirements approaches is that the region's employment or income structure is compared to a sample of similarly sized counties or regions rather than the nation as a whole. For each economic sector, the county within the size class (e.g., based on population) that has minimum share of its employment or income devoted to that sector is identified. Every other county within the size class is then assumed to produce exports, with its export activity consisting of the difference between a sector's share of employment or income in the region and the sector's share in that county where the minimum share occurred.

In addition to these methods being used to build impact assessment methods and tools, the simple methods have proven to provide powerful insights into the strengths, and weaknesses, of local economies. Because of their simplicity, local decision makers are likely to understand and hence use the information gained by their application. Still, even as these simple bifurcation methods have been criticized, they at the same time have been the focus of numerous refinement procedures (e.g., Pratt, 1968; Archer, 1976; Isserman, 1980; LeSage and Reed, 1989).

For example, researchers have employed dynamic location procedures to estimate basic employment or income or they have employed confirmatory factor analysis. Harris *et al.* (1998) employed confirmatory factor analysis to estimate sectoral basic employment and income for a given region. This procedure assumes that basic employment or income is unobservable and that procedures such as the assignment procedure, LQs, and minimum requirements are imperfect estimates of the basic sector activity. These indirect procedures, although not perfect, provide some indication of the unobservable latent variable which is export or basic activity. Using confirmatory factor analysis (Bollen, 1989), a relationship among a set of indicators of basic employment or income can be employed to derive the unobserved latent variable sectoral basic employment or income. Additional explanation of these procedures and enumeration of limitations are addressed by Shaffer *et al.* (2004).

Oversimplification

Base models have been criticized for being simplified in that they assume that a shift in export demand is the sole source of change in local economic activity. There are many additional factors that affect economic activity, including supply factors. Size of population, labor availability and skill level, and entrepreneurship activity, to name a few would likely influence local economic activity in contemporary America more than just expanded export sales. The notion of promoting economic growth through building stronger linkages within the local economy, for example, cannot be addressed in export-base theory. Also the theory neglects imports and the multiplier effect of 'import substitution.'

Stability of basic and nonbasic multipliers over time

Economic base models are justified by the existence of a long-run relationship between basic and nonbasic sectors: basic or export sectors buy inputs from local nonbasic and as the export sector grows, nonbasic sector activity also grows. Some past studies (Shahidsaless *et al.*, 1983; Braschler, 1972; Mandelbaum and Chicione, 1985; Mulligan and Kim, 1991) employed single-time period cross-sectional data. Cross-sectional studies, unfortunately, are static in nature and any examination of change during one period alone could be misleading.

Other studies employed monthly or quarterly time-series data to test for short-run and long-run multipliers (Henry and Nyankori, 1981; Spreen and Mulkey, 1980; Lego *et al.*, 2000; Harris *et al.*, 1999). With time-series models, cointegration is applied to test for long-run relationships between variables such as basic and nonbasic employment or income. Nishiyama (1997) found that economic base theory through cointegration holds strongly for the crudest definition of base such as the assignment method but not for other base definitions for the states of California, Massachusetts, and Texas. As noted in Section Oversimplification, the definition of the local economy or region matters: it has been argued that small isolated economies rather than large state or metropolitan economies are more appropriate for export-base models. Harris *et al.* (1999) and Lego *et al.* (2000) employed cointegration to show linkages between basic and nonbasic economic sectors and dynamic multipliers through vector autoregression models. Results of both studies show that export employment in a sector such as agriculture could yield negative short-run multipliers but employment multipliers that are positive in the long-run. Short-run negative multipliers could be due to the lag of labor migrating from other areas to the study area and the basic sectors offering above average wages thereby bidding away employment from local nonbasic sectors. Given a longer time period the study area labor force increases due to in-migration and both basic and nonbasic employment increases.

These previous base model studies aggregate basic and nonbasic employment or income into one sector. To derive differential sectoral impacts, differential export-base models were developed. Vias and Mulligan (1997) and Weiss and Gooding (1968) derived disaggregated multipliers for small areas but the number of disaggregated sectors were limited to four or fewer. The results of disaggregation were less than desirable in that the number of disaggregated base sectors was limited by degrees of freedom for statistical significance. Interindustry or IO models became more commonly used because of their ability to estimate detailed distributional impacts.

Vollet and Bousset (2010) employed meta-analysis to derive export/economic base multipliers. This procedure found

the area size, how the export/base sector was identified, and if the export/base sector was based on employment or income greatly impacts the multiplier estimation.

Although some export/base bifurcation procedures can appear to be overly simplistic, tools such as LQs have proven to be conceptually and empirically powerful for understanding local economies. Despite the limitations, these tools have stood the test of time and are still used for a range of economic development policy analysis in addition to impact assessment, such as industrial cluster analysis (e.g., Goetz *et al.*, 2009).

Input–Output Models

Given the need for more disaggregated sectoral information from impact analysis, IO models have been employed since they were first developed by Leontief (1936) in the 1930s. The original IO models developed by Leontief were national and used to derive impacts from national agricultural policy changes. Originally envisioned as a system of national income accounts, the power of the Leontief approach lies is in its ability to model ripples (i.e., impacts) throughout the economy and measure economic multipliers.

State, regional, and local policy decision makers requested similar analysis of potential local impacts of changes from public policies affecting their local agricultural sectors. At the time, however, national production functions could not be transferred to subnational study areas and resulting analysis was unsatisfactory. Desiring subnational IO models, a series of survey-based IO models were developed in Texas (Grubb, 1972), Washington State (Bourque *et al.*, 1967), West Virginia (Miernyk *et al.*, 1970), and Kansas (Emerson, 1969). These survey-based models were, and still are, expensive and required substantial time to be completed.

Given the dissatisfaction with direct survey models, several nonsurvey procedures were subsequently developed. These nonsurvey procedures employed traditional and alternative LQs procedures and supply–demand procedures to derive regional and county IO models. Researchers found that data collection and programming these indirect procedures were again time consuming and costly.

With increases in computing power the US Forest Service developed the IMPLAN IO modeling system (Alward and Palmer, 1993). IMPLAN provided software and data that could easily and inexpensively be used to create regional and county IO models for policy analysis. The IMPLAN modeling system was later commercialized as Minnesota IMPLAN. This software program became popular among government, university, and private sector users. The application of the IMPLAN software was expedited by a workshop sponsored by United States Department of Agriculture and the Regional Development Centers in 1988 in Ft. Collins, CO, USA. This training greatly expanded the use of IO models by University Cooperative Extension faculty to address impact issues from changes in agricultural policy. As noted, many studies have investigated the impacts of the agricultural sector on the state economy, and Leones *et al.* (1994) found that about half of these studies used IO models. IO models have also been employed to provide regional impacts from natural disasters and changes in public policies as they impact the agricultural sector.

Nonsurvey methods and models need to be verified and validated. Holland *et al.* (1997) provided a detailed procedure for doing this for IMPLAN. McKean and Spencer (2003) investigated the possibility that IMPLAN may understate agricultural sector impacts. Also some have found the agricultural sector scheme from IMPLAN to be too aggregated and that other secondary data procedures need to be employed to address specific agricultural sectors and agricultural policy questions. Procedures outlined by Coupal and Holland (1995) showed how University Cooperative Extension agricultural budget fact sheets can be used to develop disaggregated agricultural sectors for specific modeling analysis. The procedures have been applied to numerous studies to analyze crop and livestock specific policies and issues for impact analysis (Coupal and Holland, 1995; Fadali and Harris, 2006).

To complete the validation and verification of the IO model, procedures outlined by Lahr (1993) should be followed to develop what is called a hybrid or mongrel model. Lahr (1993) suggested completing direct interviews of resource sectors, miscellaneous sectors, and other key sectors of interest. Collecting sectoral information as a percentage of total output that are exports and total inputs that are imports increases the validity of the model. The IMPLAN model to its credit allows easy modifications to its database for this specific analysis.

Numerous studies investigating economic linkages and impacts of the agricultural sector have been conducted for single counties, regions, states, or even nations. Hughes and Litz (1996) developed an interregional IO model of the Monroe Louisiana Functional Economic Area employing the IMPLAN model. Their model estimated the contribution of agriculture in the rural periphery to the urban core. Their study showed economic linkages between the urban food processing sector and the rural periphery economy to be small. Interregional studies such as Hughes and Litz (1996) may become more important, as growing metropolitan populations may not understand the economic linkages between their cities and the rural agricultural periphery.

Social Accounting Matrix Model

Impact analysis from changes in agricultural activity from IO models primarily shows total output, employment, and income impacts. By the 1990s interest was not limited only to total impacts but also the distributional consequences of different agricultural policies and production levels on the regional economy. SAM models were developed to identify the distributional impacts of agricultural activity changes. One of the primary results of a regional IMPLAN derived SAM model is the disaggregation of households by income size. This allows one to derive the distributional impacts of agricultural sector output changes or public policies on a regional economy. Holland and Wyeth (1993) discussed similarities and differences in IO and SAM multipliers. SAM models have also been applied to agriculture and forestry for analysis of distributive economic impacts (Breisinger *et al.*, 2010; Bautista, 2001; Marcouiller *et al.*, 1993). Waters *et al.* (1999) employed SAM modeling procedures to estimate the agricultural sector's role in Oregon's economic base. The SAM allowed for federal

transfer payments into the base analysis, which provided unique insights.

Conjoined Econometric/Interindustry Model

With IO and SAM models, resulting impact analysis shows only total economic and distributional impacts. The analysis generally followed a 'with' and 'without' framework with no discussion of how these impacts proceed over time. Public policy questions arise as to impacts to local government revenues and expenditures, and demographics, and local government services. To include these additional factors conjoined econometric/IO, models have been developed. Rey (2000) and Shields (2006) showed the conjoined econometric/IO model provides several advantages over IO or SAM models and sophisticated econometric models. As noted in Shaffer *et al.* (2004) the use of the simple Keynesian system of economic accounts has provided the theoretical foundation for a wealth of statistically (econometric) derived models of national and state economies. These models are widely used for both policy or impact analysis (Shields *et al.*, 2001) and forecasting (see Johnson *et al.* (2006) for a detailed discussion of a particular family of conjoined models and their applications).

With the widespread use of IOs and SAMs at the local level, primarily through the application of IMPLAN, economists are exploring ways to leverage the power of IOs and SAMs with the power of statistical models. Because both IO/SAM and econometric approaches have attractive features, it was inevitable that economists would try to select the most promising attributes of each in developing a hybrid model. These models that use both IO/SAM and econometrics are often referred to as integrated or conjoined. In his 1977 presidential address to the American Economics Association, Nobel Laureate Lawrence Klein suggested that models that integrate IO/SAMs and econometric methods might become a new method or approach to guide our thinking about the performance of the economy.

In an integrated or conjoined model, the IO/SAM component is used to determine industry supply and primary factor demands. The econometric component determines final demands, factor prices (hence price endogenous), primary factor supplies, and financial market variables. The aim is to retain the sectoral detail of the IO/SAM and close the model with a system of endogenous econometric relationships. The closure mechanism links primary factors and final demand.

Hybrid conjoined models offer several important benefits from an applied perspective. First, the IO/SAM component allows for more sectoral detail, or disaggregation, than the traditional econometric or CGE approaches. Second, the econometric equations provide a better mechanism for introducing policy simulations by fully specifying the underlying components of final demand. Third, the full employment assumption of IO/SAM can be relaxed – the econometric component allows for unemployment or underutilization of local resources. Fourth, the econometric components can accommodate spatial issues that are of particular importance to communities, such as migration and commuting. Finally, the econometric components explicitly allow prices to fluctuate.

There are, unfortunately, limitations to these conjoined models. First, there is no commonly accepted way to link the IO/SAM and econometric elements of the model, specify the econometric equations, or choose among alternative econometric methods. Second, the required time-series data at the local level can be difficult to obtain. As a result, two competing models can yield different policy results depending on how the model builder approaches model construction and estimation.

Computable General Equilibrium Model

IO, SAM, and conjoined econometric/IO-SAM models cannot be used for welfare analysis. This is where CGE models can be employed. Just like the original IO models of the 1930s, the success of these national models for analysis of public policies led to a demand for similar work at the state, regional, and county levels. One of the problems with IO-SAM and export-base derived models is that prices are fixed and not allowed to vary. For economists this is particularly troublesome because prices are the market clearing mechanism. To use an economic model that does not readily allow prices to change is troublesome, and the advent of CGE models directly addressed this fundamental problem. Development of CGE models, however, was fairly complex and they were not widely used. The data from IMPLAN modeling of SAM's, the development of General Algebraic Modeling System and enhance computing power provided researchers and Cooperative Extension personnel the tools to develop subnational CGE models.

CGE models are based on the Walrasian general equilibrium structure. The models explicitly incorporate supply constraints, identify prices and quantities separately, and assume twice-differentiable production and preference surfaces. Thus unlike IO and SAM models, CGE models allow substitution effects in production and consumption. Factor and commodity markets attain their equilibrium through adjustment of prices. There are several CGE models in the literature (Seung *et al.*, 2000; Waters *et al.*, 1997; Schreiner *et al.*, 1996; Hoffman *et al.*, 1996; Kraybill *et al.*, 1992; and Berck *et al.*, 1991). Seung *et al.* (2000) analyzed water reallocation policies in rural Nevada and compared water reallocation policies employing compensating variation. Additionally, Schreiner *et al.* (1996) used CGE modeling as a framework for economic development and showed that policies for increased employment or higher aggregate output levels could produce results that were lower than welfare maximization policies. Given increased application of CGE models and potential advances by IMPLAN to produce synthesized CGE models the use of CGE models should increase.

CGE models, as with any economic model, have their limitations. Because of the complexity of these models industrial detail is lost compared to an IO/SAM model. For example, all of agriculture is commonly aggregated into one sector. Modelers must at times make heroic assumptions to operationalize the model. For example, exactly how sensitive are the demand for and supply of agricultural commodities? Or exactly how does the local economy interact with the larger surrounding economy? Exactly how do consumers and firms

respond to tax policies? Each of these plus dozens of other issues must be quantified in detail and often researchers must make strong assumptions to operationalize the models.

Alternative Metrics for Impact Analysis

With employment of various models to derive economic linkages of the agricultural sector to other sectors in the economy and resulting economy-wide changes from alternative agricultural production levels due to natural disasters, export expansions, or governmental policies, alternative metrics employed in the use of these models needs to be addressed. Watson *et al.* (2007) provided an overview of alternative metrics for assessing how changes in agriculture affect the study area economy. They discussed contribution analysis, impact analysis, and benefits or welfare analysis. An understanding of the differences in these metrics provides researchers and reviewers of economy-wide studies with a perspective on proper procedures for analyzing regional economic changes from agricultural activity. Incorrect application of an impact research metric can yield errors in the analysis which then undermines the analysis in the eyes of the funding agency and public.

Contribution analysis yields estimates of gross change in economic activity and the resulting respending of dollars in a local economy. The contributions metric as defined by Watson *et al.* (2007) is based on a purely descriptive analysis that simply tracks gross economic effects and does not address crowding out of other sectors or economic activity. Impact analysis, however, examines the effect of new revenues to the study area or of keeping revenues in the area that would otherwise leave. Especially in studies of tourism, impact analyses encompass the concept of 'displacement.' Displacement in this case refers to expenditures by local tourists that would have been spent on other sectors of the economy if the tourism activity had not existed. Given a fixed amount of money for recreational expenditures, how do local residents spend those dollars? Therefore, this would represent only recycling of dollars that already exists and not new dollars coming into the study area (if the tourists are not from outside the area). For example, does a local agritourism event draw from only the local community or does it attract tourists from a larger geographic area? If the local agritourism event draws from only the local community, what other recreational activities in the community are affected or displaced?

Cost–benefit analysis is yet another means of assessing changes in a rural economy. Cost–benefit is an overall economic efficiency or social welfare analytical concept which employs compensating or equivalent variation. Boardman *et al.* (2001) and Schreiner *et al.* (1996) discussed that benefit analysis usually draws on what economists call Kaldor–Hicks welfare analysis while applying CGE models. These CGE models are complex representations of simple supply and demand relationships. Shocks to the local economy, such as a change in agricultural exports, shift those supply and demand relationships resulting in different prices and quantities produced and consumed. The cost–benefits of those shifts are captured through consumer and producer surplus. Here consumer surplus is the difference between the maximum price a consumer is willing to pay and the actual price they do pay for a good or service. Producer surplus is the amount that producers benefit by selling at a price that is higher than the least that they would be willing to sell for. Although these concepts are intuitive to an economist, they often are less intuitive to policy makers and concerned citizens. This is an area for extension economists to address as to outreach programs to convey an understanding of welfare analysis with economy-wide models.

Differences in results from cost–benefit analysis, when compared to impact procedures, can arise when the public is better off in ways that are not tractable by economic activity. For instance, residents in a rural area may be happier spending US$50 for a local agritourism event than spending the same amount on a close substitute, for example a concert. If this is the case, as Watson *et al.* (2007) enumerated, the actual economic activity in the rural area has not changed but the net benefits, or welfare, to the rural residents has increased. For this reason, it is important to understand that contribution or impact analysis should not be confused or mistaken for cost-benefit analysis.

Additionally, the impacts by size of the study area should be addressed. Usually the study area is defined by groups funding the study. The study area is usually a county, a region defined by a grouping of counties, or an entire state. The geographic boundaries of a study area limit impacts to a given area. For example, a small rural ranching area which experiences a reduction in public cattle grazing will have large local economic impacts. If, however, the study uses the nation as a region, then the impacts from reduction of public grazing in one small rural county will have relatively small national impacts. Therefore, the area of study becomes profoundly important if public policy issues are to be formulated correctly from the results of economy-wide models.

Conclusion

Given the demographic and economic structural changes in nonmetropolitan economies as well as the structural changes in the agricultural sector itself, understanding and proper use and application of economy-wide models for public policy analysis is paramount. This article has attempted to provide a succinct review of models that have and can be used to analyze the economic linkages and impacts of the agricultural sector to a county, regional, interregional, or national economy. This article reviewed several historical quantitative procedures to estimate the agricultural sector's contribution to the economic base of an economy, and how these models can be modified to increase verification and validity. The article also addressed differences in economy-wide model metrics that can be used and how the incorrect application of a metric may provide erroneous results. Lastly, the importance of considering the size of the study area was stressed. Geographic boundaries limit the impacts that vary from the national to the local perspective. Proper metrics and study area are essential for ensuring that studies are publically accepted. The article did not address fiscal or social impacts that will arise from changes in agricultural activity. These activities must also be included

for a comprehensive analysis of changes in agricultural production or public policies that impact the agricultural sector.

Glossary

Adjuvant A substance that enhances the body's immune responses to an antigen.

Aflatoxins A toxic compound produced by certain molds found in food, which can cause various pathological problems (liver and kidney damage, immunosuppression, and tumors).

Allele Each of two or more alternative forms of a gene that arise by mutation and are found at the same place on a homologous chromosome.

Apoptosis A genetically determined process of cell self-destruction that is marked by the fragmentation of nuclear deoxyribonucleic acid (DNA); is activated either by the presence of a stimulus or by the removal of a stimulus or suppressing agent; is a normal physiological process eliminating DNA-damaged, superfluous, or unwanted cells; and when halted (as by genetic mutation) may result in uncontrolled cell growth and tumor formation – also called programmed cell death.

Astrocytosis An increase in the number of astrocytes, frequently observed in an irregular zone of variable definition adjacent to degenerative lesions (encephalomalacia), focal inflammations (abscesses), or certain neoplasms in the brain; in some instances, astrocytosis may be diffuse in a relatively large region; it represents a reparative mechanism.

B haplotype Major histocompatibility complex of the chicken.

Bursa of Fabricius A primary lymphoid organ that opens into the cloaca of birds and functions in B-cell production.

Demyelination A degenerative process that erodes away the myelin sheath which normally protects nerve fibers.

Edematous Affected with edema (an excessive accumulation of serous fluid in tissue spaces or a body cavity).

Encephalomalacia The softening of the brain due to degenerative changes in nervous tissue (as in crazy chick disease).

Encephalomyelitis The inflammation of the brain and the spinal cord. In young poultry, encephalomyelitis is induced by a picornavirus (avian encephalomyelitis virus).

Feather follicle epithelium The layer of the epidermis surrounding the feather follicle (a small tubular invagination of the skin with a fleshy dermal papilla at the bottom from which the feather grows. The papilla is inserted in the opening at the end of the quill).

Feather pulp The remnants of vascular tissue contained in the core of each feather.

Flaccid paralysis A clinical manifestation characterized by weakness or paralysis and reduced muscle tone without other obvious cause (e.g., trauma).

Gliosis A nonspecific reactive change of glial cells in response to damage to the central nervous system (CNS). In most cases, gliosis involves the proliferation or hypertrophy of several different types of glial cells, including astrocytes, microglia, and oligodendrocytes. In its most extreme form, the proliferation associated with gliosis leads to the formation of a glial scar.

Heterophil Leukocyte in avian species equivalent to neutrophils in mammalian species.

Immunohistochemistry The microscopic localization of specific antigens in tissues by staining with antibodies labeled with pigmented material.

Immunomodulator The agents that alter the immune response by suppression (immunosuppressive) or enhancement (immunostimulant).

Infectious laryngotracheitis A respiratory disease of chickens caused by an alphaherpesvirus (*Gallid herpesvirus 1*). It is characterized by severe inflammation of the larynx and trachea that lead to coughing, sneezing, head shaking, lethargy, discharge from the eyes and nostrils (sometimes bloody), and difficulty breathing.

Keratitis The inflammation of the cornea.

Lymphoblastoid Resembling a lymphoblast.

Lymphodegenerative The degeneration of the lymphoid tissue.

Lymphohistiocytic Involving lymphocytes and histiocytes.

Major histocompatibility complex (MHC) A set of molecules displayed on cell surfaces that are responsible for lymphocyte recognition and 'antigen presentation.' The MHC molecules control the immune response through

 doi:10.1016/B978-0-444-52512-3.00193-5

recognition of 'self' and 'nonself' and, consequently, serve as targets in transplantation rejection.
Oncogene A gene that causes normal cells to become cancerous either because the gene is mutated or because the gene is expressed at the wrong time in development.
Oncogenic Tending to cause or give rise to tumors.
Panolphtalmitis The inflammation of all the eye structures or tissues.
Parenchyma The specialized epithelial portion of an organ, as contrasted with the supporting connective tissue and nutritive framework.
Pathognomonic Characteristic or symptomatic of a particular disease or condition.
Pectenitis The inflammation of the pecten (a vascular pigmented membrane projecting into the vitreous humor within the globe of the eye in birds).
Perifollicular Surrounding a follicle (either hair or feather follicle).
Pleomorphic Occurring in various distinct forms. In terms of cells, having variation in the size and shape of cells or their nuclei.
Polyneuritis Neuritis involving several nerves simultaneously.
Quantitative trait loci (QTLs) Stretches of DNA containing or linked to the genes that underlie a quantitative trait.
Real-time polymerase chain reaction (PCR) A technique used to monitor the progress of a PCR reaction in real time.
Reticuloendoteliosis A group of pathological syndromes in several avian species caused by reticuloendotheliosis virus, a member of the avian retrovirus group.
Retinitis The inflammation of the retina.
Serotype A group of closely related microorganisms distinguished by a characteristic set of antigens.
Single-nucleotide polymorphism A DNA sequence variation occurring when a single nucleotide – A, T, C, or G – in the genome (or other shared sequence) differs between members of a biological species or paired chromosomes.
Spastic paralysis An abnormal condition characterized by the involuntary contraction of one or more muscles with associated loss of muscular function.
Torticollis A condition in which the head becomes persistently turned to one side, often associated with painful muscle spasms.
Toxoplasma A parasitic spore-forming protozoan (genus *Toxoplasma*, phylum Sporozoa) that can sometimes cause disease in humans and animals.
Uveitis The inflammation of the uvea.
Vasculitis The inflammation of a blood vessel or blood vessels.

Introduction

Marek's disease (MD) is a highly contagious lymphoproliferative disease of chickens caused by an alphaherpesvirus of the Genera *Mardivirus* (ICTVdB-Management, 2006). In the absence of proper control methods, MD constitutes one of the major threats for the poultry industry. Vaccination against MD has been used since the late 1960s with great success (Churchill *et al.*, 1969). However, Marek's disease virus (MDV) has evolved toward increased virulence within the last 50 years (Witter, 1997) and the ability of MD vaccines to control the disease has consequently decreased. Even using adequate vaccination, in 1984, Purchase estimated mortality and condemnation losses associated with MD at US$169 million in the US and at US$943 million worldwide (Purchase, 1985).

In addition to lymphomas, MDV is able to induce a variety of nonneoplastic syndromes, such as neurological syndromes, immunosuppression, and arteriosclerosis. The economical impact of the MDV-induced nonneoplastic syndromes is difficult to estimate but might be more relevant than initially thought, especially MDV-induced immunosuppression (MDV-IS).

Diagnosis of MD is sometimes complex due to the similarity between MDV-induced tumors and neoplasia induced by other viruses (i.e., avian leukosis virus and reticuloendotheliosis). In addition, some nonneoplastic syndromes, like peripheral neuropathy, are characterized by peripheral nerve lesions very similar to those induced by MDV. An accurate diagnosis is extremely important to establish the proper control methods. Besides confirming a diagnosis, in the event of an outbreak of MD, it is necessary to analyze the possible causes that might have led to the breach on MD vaccine immunity.

MD vaccines are cell associated and that makes their handling and storage difficult. Many outbreaks of MD have been related to failures on vaccination procedures that led to reduced vaccine doses. However, other factors have also been associated with MD outbreaks, such as early infection with MDV (before vaccines can establish immunity), concomitant immunosuppressive diseases, or presence of emergent more virulent MDVs in the area.

The goal of this article is to review the different syndromes induced by MDV focusing mainly on those of more economical relevance for the poultry industry. This article reviews the methods to diagnose MD and to differentiate MD from other related diseases. Finally, currently available vaccines and vaccine protocols are discussed.

Etiology

MDV is an alphaherpesvirus belonging to the genus *Mardivirus* and the subfamily Alphaherpesvirinae. According to the International Committee on Taxonomy of Viruses, members of the genus *Mardivirus* are divided into three species, viz. *Gallid herpesvirus 2* (formerly named MDV serotype 1), *Gallid herpesvirus 3 (*formerly named MDV serotype 2), and *Meleagrid herpesvirus 1* (formerly named MDV serotype 3). The original classification in serotypes was based on the recognition of common and distinct antigenic epitopes for each serotype

(Bülow *et al.*, 1976). Furthermore, each serotype has unique biological features. Serotype 1 MDVs are oncogenic viruses of chickens. Based on their virulence, serotype 1 MDV can further be classified into pathotypes (Witter, 1997). To date, four pathotypes have been described: mild (m), virulent (v), very virulent (vv), and very virulent plus (vv+). Serotype 2 MDVs are nononcogenic viruses of chickens (Schat and Calnek, 1978a). Serotype 3 MDVs are nononcogenic viruses of turkeys and are commonly named as turkey herpesvirus or HVT (Witter *et al.*, 1970). The original classification in serotypes has recently been justified on the basis of the complete sequence for serotype 1 Md5 and GA strains (Lee *et al.*, 2000; Tulman *et al.*, 2000), serotype 2 HPRS-24 strain (Izumiya *et al.*, 2001), and serotype 3 FC126 strain (Afonso *et al.*, 2001). In this article, the term MDV indicates serotype 1 MDV because virulence is unique for this serotype. Related herpesviruses of serotypes 2 and 3 are indicated by the serotype.

MDV has unique features that differentiate it from any other alphaherpesvirus (Schat and Nair, 2008). It is a cell associated with lymphotropic properties similar to those of gammaherpesvirus. It establishes latency in lymphocytes. Furthermore, it carries an oncogene (meq) and is able to transform latently infected lymphocytes into neoplastic cells. However, its molecular structure and genomic organization are similar to alphaherpesvirus (Buckmaster *et al.*, 1988); hence, it is classified into this group of viruses. The details on the genome structure of MDV exceed the objectives of this article and readers are encouraged to read other articles for detailed information (Schat and Nair, 2008).

MDV can establish three different kinds of interaction with the host cells: productive infection, latent infection, and transforming infection. Productive infection implies replication of viral deoxyribonucleic acid (DNA), synthesis of viral protein, and in some cases, production of viral particles. Based on the production of viral particles, there are two kinds of productive infection: fully productive infection and restrictive productive infection. Fully productive infection results in the development of large numbers of enveloped, fully infectious virus. This kind of infection occurs only in the feather follicle epithelium (FFE) and is of major importance in the epidemiology of the disease, as it is the main, if not the only, source of infectious MDV particles (Calnek *et al.*, 1970). Restrictive productive infection results in the development of nonenveloped virions. Several cell types are permissive for restrictive productive infection. *In vivo*, B cells are the principal target cells but activated T cells, macrophages, and transformed cells can also support restrictive productive infection (Calnek, 2001). *In vitro*, this kind of infection can be observed in chicken kidney cells, chicken embryo fibroblast, duck embryo fibroblast, B cells, and other cell lines from chicken origin. Latent infection is defined as the presence of viral genome with no or limited production of viral antigens or infectious virus (Morgan *et al.*, 2001). During latency, transcription of viral DNA is minimal and there are very few copies of viral DNA per infected cells. For serotype 1 strains, the distinction between latency and transformation is problematic and most of the studies of latency are conducted either using other nononcogenic serotypes or in transformed cell lines. Activated T cells are the target cells for latent infection, but latency has also been reported in a small proportion of B cells and in satellite cells and nonmyelinating Schwann cells of peripheral nerves and spinal ganglia (Pepose *et al.*, 1981). Transforming infection occurs only in cells infected with serotype 1, because other serotypes have no oncogenic potential. Transcription of viral DNA is still low but higher than in latent infection. Activated T cells, mainly of phenotype CD4+CD8−, are the target cells for transformation. Viral antigen expression during transforming infection is very restricted and is further discussed under the diagnosis section of this article.

MDV has increased in virulence within the past 50 years (Witter, 1997). Before the industrialization of the poultry industry in the 1950s, MDV strains were mild in virulence and were characterized for inducing a mild polyneuritis in older chickens with no major economical significance (Marek, 1907; Pappenheimer *et al.*, 1929). In the 1950s, a major switch in MDV occurred that jeopardized the onset of the poultry industry. MDVs became oncogenic and were able to induce not only a polyneuritis syndrome but also widespread lymphomas with mortality up to 50% of the flocks (Biggs *et al.*, 1965; Eidson *et al.*, 1968). Those viruses are currently known as virulent MDV (vMDV) (Witter, 1997). The introduction of MD vaccines in the late 1960s (Churchill *et al.*, 1969; Witter *et al.*, 1970) controlled the more severe form of the disease for approximately 20 years. The most widespread vaccine used at that time was serotype 3 MDV (HVT) (Witter *et al.*, 1970). However in the 1980s, a second switch of the virus occurred and led to decrease efficacy of HVT (Witter *et al.*, 1980). Those emergent viruses are currently known as very virulent MDV (vvMDV) and forced the poultry industry to introduce a new vaccine based on combination of HVT and serotype 2 viruses known as bivalent vaccine (Witter, 1982; Calnek *et al.*, 1983). The efficacy of the bivalent vaccine got reduced again in 1990s when another switch of the virus took place. Those are the currently existing viruses and are known as very virulent plus (vv+MDV) (Witter, 1997). The only vaccine currently available that can control vv+MDV is an attenuated serotype 1 MDV strain named CVI988 or Rispens (Rispens *et al.*, 1972; Witter *et al.*, 1995).

Biologically, the newly emergent more virulent MDVs differ clearly from less virulent MDVs. They are able to break vaccine immunity and this is the criteria for the gold standard pathotyping system (Witter *et al.*, 2005); they are more neurovirulent (Gimeno *et al.*, 2002); they might have expanded the host range (Gimeno, 2008); and they seem to be more immunosuppressive (Calnek *et al.*, 1998). Molecularly, however, there are minor changes among vMDV, vvMDV, and vv+MDV (Spatz and Silva, 2007) and at this point it has not been possible to establish a pathotyping system based on molecular features.

The causes of MDV evolution are not well elucidated but some hypotheses have been proposed. The changes in poultry production systems during the 1950s could be a major trigger for the initial changes in MDV leading to a new manifestation of the disease. The occurrence of all subsequent waves of evolution of virulence had been linked to the introduction of different generations of vaccines (Gimeno, 2008). The observation that viruses from each successive wave acquired the ability to overcome the immunity induced by the previously used vaccine strongly suggests that the evolution is primarily aimed at avoiding/overcoming the vaccine-induced response.

The fact that none of the current MD vaccines induce sterilizing immunity or prevent challenge viruses from being released could be a major trigger for the evolution of MDV.

Epidemiology

Chickens are the most important natural host for MDV, but quail, turkeys, and pheasants are also susceptible to virus infection and disease (Witter and Schat, 2003). It is suspected that more virulent MDVs have increased ability to induce disease in turkeys than less virulent MDVs. This work addresses the clinical and pathological manifestation of MD in chickens. A more detailed description of the disease in other species can be found in Gimeno *et al.* (2003) and Schat and Nair (2008).

MDV infection occurs by the airborne route. Transmission of the infection occurs readily between chickens by direct or indirect contact. Epithelial cells in the keratinizing layer of the FFE support fully productive infection and these cells serve as a source of contamination to the environment and to other chickens. Virus is generally associated with desquamated, keratinized FFE cells that are shed along with molted feathers and as dander. Virus excretion begins approximately 2 weeks postinfection (wpi) (Kenzy and Biggs, 1967), with a maximal shedding occurring between the third and the fifth wpi (Witter, 1972). Once the infection has been introduced into a chicken flock, regardless of vaccination status, infection spreads quickly from chicken to chicken. Replication of the virus in the feather follicle can be detected by the existence of nuclear inclusion bodies in the infected cells or by evaluation of the expression of MDV antigens. Vertical transmission of MDV has not been reported.

Vaccination does not prevent superinfection, which is a major factor in the evolution of MDV toward more virulence. Vaccinated chickens become a perfect ecosystem in which a variety of MDVs replicate and those better fit to avoid the immune system have an advantage to spread in the flock. Recently, Dunn *et al.* have evaluated the consequences of superinfection and the factors that influence the outcome of the infection when superinfection occurs (Dunn *et al.*, 2010).

Pathogenesis

MDV is able to induce a variety of syndromes that are divided into two categories: nonneoplastic and neoplastic. The latter is by far the most relevant for the poultry industry due to the economical repercussions and it is referred to normally as MD. The impact of the nonneoplastic syndromes is less understood and it is discussed in the section clinical signs and lesions of this article. Pathogenesis of MDV is a very complex process and a detailed discussion is beyond the scope of this article. Further details can be found in numerous review papers (Schat and Nair, 2008; Calnek, 2001). In this article only those events of the pathogenesis that are relevant to the development of the different MDV-induced syndromes are reviewed. The pathogenesis of MDV differs in chickens that have maternal antibodies (MAb) against MDV and those lacking MAb. In this section, events occurring after infection of chickens lacking maternal antibodies are described. **Tables 1** and **2** summarize the differences on the pathogenesis of MDV in chickens with and without MAb.

The natural route of MDV infection is via respiratory tract following inhalation of infectious cell-free MDV from a contaminated environment. The role of the lung in MD pathogenesis is not clear and it is presumed that phagocytes present in the lung pick up the virus and carry it to lymphoid organs, such as bursa of Fabricius, the thymus, and the spleen. At this early point in the infection, there is no associated pathology in the lung; however, viral antigen has been detected in

Table 1 Pathogenesis of Marek's disease virus in chickens lacking maternal antibodies

Days postinoculation	*Viral infection*	*Lesions*	*Clinical signs*
0	Lung	None	None
3–6	Lymphoid organs	Lymphodegenerative syndromes	Depression Transient immunosuppression
2–7 on	Blood	None	None
7–14	Brain	Brain edema and vasculitis	Transient paralysis
	Nerves	Neuritis	None

	Other tissues	Inflammation	None
10-on	Feather follicle epithelium	None	None
14-on	Nerves, viscera, and brain	Tumors	Variable
21-on	Arteries	Arteriosclerosis	None

Table 2 Pathogenesis of Marek's disease virus (MDV) in chickens with maternal antibodies against MDV

Days postinoculation	*Viral infection*	*Lesions*	*Clinical signs*
0	Lung	None	None
3–6	Lymphoid organs	None	None
2–7	Blood	None	None
10-on	Feather follicle epithelium	None	None
14-on	Nerves, viscera, and brain	Tumors	Variable

parenchymal cells (Adldinger and Calnek, 1973; Phillips and Biggs, 1972; Purchase, 1970).

MDV reaches the lymphoid organs within 24–36 h after intratracheal inoculation. In the lymphoid organs, infection of lymphocytes seems to be assisted by splenic ellipsoid-associated reticulum cells in blood vessel walls (Jeurissen *et al.*, 1992). In unvaccinated chickens lacking material antibodies against MDV, a productive cytolytic infection is established in the lymphoid organs between 5 and 6 days postinfection (dpi). The initial target cells for the cytolytic infection are B lymphocytes (Shek *et al.*, 1982). This productive infection leads to necrosis and inflammation in the lymphoid organs, inducing what is known as lymphodegenerative syndromes. At this stage, antigens are present in infected cells and virus particles can be detected by electron microscopy. Lymphodegenerative syndromes are associated with a transient immunosuppression.

The necrosis of B cells in the lymphoid organs elicits an immune response and the recruitment of numerous inflammatory cells, especially macrophages, T and B lymphocytes, and some heterophils. The activation of T cells is of particular relevance in the pathogenesis of MDV as resting T cells are refractory to MDV infection. Activated T cells can also support productive infection, but in most cases infection becomes latent after T cells are infected. The switch from cytolytic infection to latency occurs very fast and by 7–8 days evidence of cytolytic infection in the lymphoid organs is minimal, if at all. Latent infection, however, can be detected by this time not only in lymphoid organs but also in peripheral blood lymphocytes (PBL).

Latently infected PBL probably are the disseminators of MDV to other tissues of the chickens. As early as 6 dpi, MDV can be detected in the eye, brain, and in peripheral nerves (Gimeno *et al.*, 2001; Pandiri *et al.*, 2008). Depending on the virulence of the virus and the genetic resistance of the chickens, MDV can reactivate in some of the lymphocytes infiltrating the brain tissue and induce an acute inflammatory response. The consequence of this inflammatory response in the brain is the development of vasculitis and vasogenic edema, responsible for the clinical signs of transient paralysis (TP) (Swayne, 1987; Gimeno *et al.*, 2001; Abdul-Careem *et al.*, 2006; Jarosinski *et al.*, 2005). In some cases, inflammatory lesions in the brain (perivascular cuffing and gliosis) are not associated with the development of TP. Early inflammatory lesions in the peripheral nerves (neuritis) are not associated with any clinical manifestation. Early inflammatory lesions in the eye can be detected as early as 6 dpi and can progress in extension and severity until they induce panophthalmitis with complete destruction of the retina (Pandiri *et al.*, 2008).

A second wave of cytolytic infection is detected in most tissue of epithelial origin by the end of the second week after infection. Because of its relevance in transmission, productive infection of the FFE is particularly important. Replication of MDV in the FFE occurs in genetically resistant as well as susceptible birds independently of the virulence of MDV strain. It also occurs in vaccinated chickens regardless of the level of protection that vaccines confer to a particular challenge. MDV most likely is transferred to the FFE by infected lymphocytes within lymphoid aggregates that develop in the perifollicular dermis as early as 7 dpi. The lymphoid aggregates can develop either into necrotic areas consisting of FFE cells and degenerating lymphocytes (dermatitis) or into cutaneous tumors (skin leukosis).

The secondary cytolytic infection is also associated with a permanent immunosuppression. The mechanisms behind permanent immunosuppression are poorly understood. MDV is able to affect the immune system in various ways: lymphodegenerative syndromes (Calnek *et al.*, 1998), immune dysregulation of the immune responses (downregulation of major histocompatibility complex (MHC) I (Gimeno *et al.*, 2001; Hunt *et al.*, 2001), upregulation of MHC II (Calnek *et al.*, 1984; Niikura *et al.*, 2007), increase of nitric oxide (NO) (Jarosinski *et al.*, 2002)), and neoplastic transformation of T cells. Both immune dysregulation and transformation of lymphocytes can lead to a permanent immunosuppression.

Vascular changes of the major arteries have been detected as early as 15 dpi, although evident lesions of vascular sclerosis do not occur until much later in the pathogenesis (Njenga and Dangler, 1995; Fabricant and Fabricant, 1999). MDV antigens can be detected in smooth muscle cells of affected arteries as early as 1 month after inoculation. Also, cells comprising arterial lesions were found to be latently infected with MDV (Fabricant, 1985). The exact pathogenesis of arteriosclerosis is unknown, but it is thought that MDV induces necrosis in the smooth muscle cells and this, together with the known alteration in lipid metabolism, might be the initial changes in the development of arteriosclerosis (Calnek, 2001). Arteriosclerosis occurs only in unvaccinated chickens lacking maternal antibodies against MDV.

Latently infected T cells can become transformed, leading to the development of lymphomas. Transformation can occur in lymphocytes infiltrating any tissue. Therefore, MDV-induced lymphomas can be detected in the nerves, brain, skin, and any internal viscera. Clinical manifestation of MDV-induced lymphomas depends on the location and extension of the tumors. For the purpose of this article, MD is referred to as MDV-induced lymphomas. Syndromes, other than lymphomas, induced by MDV will be referred by the syndrome name.

Clinical Signs and Lesions

Incidence and economic relevance of the different MDV-induced syndromes vary. Lymphodegenerative syndromes, panophthalmitis, TP, and arteriosclerosis occur only in susceptible chickens lacking maternal antibodies and unvaccinated against MD. This is a very unlikely scenario in field conditions and therefore these syndromes are most commonly reproduced in the laboratory. TP, however, was commonly observed in 8–18-week-old pullets before the use of MD vaccines and is still a problem in 30–40-day-old broiler chickens when they are unvaccinated. Neoplastic syndromes are the most commonly observed syndromes in the field and have important economic impact. The economic impact of MDV-IS is unknown. With the exception of lymphoid organ atrophy (if lymphodegenerative syndromes occur) no specific lesions or clinical signs are associated with MDV-IS. Therefore, MDV-IS is not discussed in this section.

Figure 1 Chicken suffering of paralysis.

Neoplastic Lesions and Associated Syndromes

Clinical signs

Signs associated with the development of MDV-induced lymphomas vary according to the location of the tumors and very few are specific to MD. Stunting, depression, lethargy, paleness, and diarrhea are nonspecific clinical signs that may be observed, especially when the course of the disease is prolonged. Torticollis and tremors are characteristics of the persistent neurological disease due to the neoplastic infiltration of the central nervous system. Asymmetric progressive paralysis that evolves to complete spastic paralysis of one or more of the extremities is the most characteristic sign of peripheral nerve dysfunction (Figure 1). Involvement of the vagus nerve usually is associated with crop paralysis and gasping. Blindness appears in birds with ocular involvement and can be uni- or bilateral.

Gross lesions

The gross changes commonly present in MD are enlargement of the peripheral nerves and spinal ganglia and lymphoma formation in various organs and tissues. Skin lesions are also observed and they are more common in meat-type than in egg-type chickens.

Visceral organs

Lymphomas may occur in virtually any tissue or organ. Distribution of the tumor in a tissue or organ can be diffuse, nodular, or both. When diffuse, viscera appear enlarged, sometimes to several times the normal size, and with grayish to whitish discoloration (Figure 2). When nodular, lymphomas appear as one or several white or gray firm foci with smooth cut surface.

Integument

Skin lymphomas are mainly associated with feather follicles and are more evident in dressed carcasses. A few or several follicles become enlarged, and in severe cases lesions from several follicles coalesce. Initially, there are whitish nodules, but in some cases they appear ulcerated with brown crust formation. Comb and wattles can also be affected. Lesions in the skin of the shanks start with reddish discoloration

Figure 2 Diffuse tumor in the liver tumor. Please note the severe hepatomegaly.

(Alabama Red Leg) and tend to progress into skin tumors with crusts (Figure 3).

Peripheral nerves

Enlargement of peripheral nerves is one of the main lesions associated with MD and has important diagnostic value to differentiate between MD and lymphoid leukosis. Although visceral tumors can occur in the absence of gross nerve lesions, if nerves are affected, the diagnosis is very much simplified. Any nerve or root ganglia can be affected and the enlargement can affect a nerve uniformly along its length or it might be nodular. Lesions can be uni- or bilateral. Affected nerves or affected areas of the nerves are usually up to 2–3 times the normal thickness. In severe cases, the enlarged nerves lose their normal glistening cross-striations, have a gray or yellow discoloration, and sometimes an edematous and hemorrhagic appearance (Figure 4).

Microscopic lesions

Regardless of the location, lymphomas induced by MDV have the same microscopic characteristics. Therefore, a general description is made followed by specific characteristics of the different tissues. MD tumors can be focal, well demarcated from the normal parenchyma of the viscera, or can infiltrate and destroy the normal parenchyma. MD lymphomas consist of a mixture of small and medium lymphocytes, lymphoblast, and macrophages (Payne, 1985). Plasma cells are rarely

Figure 3 Skin tumors in the skin of thighs and shanks.

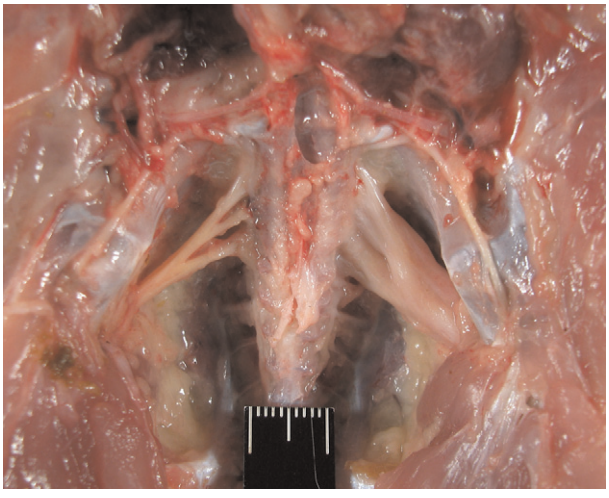

Figure 4 Unilateral tumor in sciatic plexus.

present. The lymphoid tumor cells are pleomorphic, with abundant cytoplasm containing few organelles other than mitochondria and ribosomes. The nuclei are fairly large, irregular in shape, and nucleoli are apparent. Because of the inflammatory component in MD lymphomas, it is particularly difficult to differentiate initial stages of the neoplasm from normal lymphoreactive areas or with severe inflammatory lesions induced by MDV.

Peripheral nerve

Peripheral nerve lesions have been classified in two types – A and B (Payne and Biggs, 1967). Type A is characterized by a massive infiltration of neoplastic cells that destroy the structure of the nerve. Microscopic characteristics of the lymphomas in nerves are the same as those described in other tissues. Type B lesions are inflammatory in nature and are characterized by infiltration of the plasma cells, edema, and different degrees of demyelination. The pathogenesis of type B lesions is poorly understood, but chronological studies have showed that they occur late in the pathogenesis of MD and appear after type A lesions, may be as an immune response against them (Lawn and Payne, 1980).

Antigen expression

Tumor cell phenotype

The complex composition of MD tumors makes the evaluation of the phenotype of the neoplastic cells difficult. Immunohistochemical analysis of MDV-induced tumors reveals that the majority (60–80%) of lymphoma cells are T cells, and most of the other cells (10–20%) are B cells, with small proportion of nonlymphoid cells, such as macrophages (Payne, 1985). It is considered that neoplastic cells are included in the T cell component because lymphoblastoid line cells and transplantable lymphoma cells derived from primary MD lymphomas are all T cells, carry MATSA, and contain multiple copies of MDV genome. Tumor cells also express high amounts of the antigen AV37, an analogous to the human CD30 antigen (Burgess *et al.*, 2001; Ross *et al.*, 1997). Although experimentally MDV is able to transform cells of a variety of cell types, under natural conditions most of the neoplastic transformed cells are considered to be CD4 + CD8 − T cells expressing the antigens MATSA and AV37.

Marek's disease virus antigens

Expression of MDV antigens is quite restrictive in transformed T cells. Sporadically, a few cells in the tumors express early antigens, such as pp38 and ribonucleotide reductase. The expression of these antigens is inconsistent and varies greatly from tumor to tumor. It is now considered that cells expressing those early antigens might be undergoing a reactivation of the infection (Witter and Schat, 2003). The oncogene meq, however, is consistently highly expressed in lymphomas as well as in lymphoblastic cell lines.

Nonneoplastic Lesions and Associated Syndromes

Lymphodegenerative syndromes

Clinical signs

Lymphodegenerative syndromes occur only in unvaccinated chickens lacking maternal antibodies against MDV. Therefore, the relevance of these syndromes in the field is minimal. Under experimental conditions, 5–6 dpi chickens become depressed, with ruffled feathers and reluctant to move.

Gross lesions

Bursa of Fabricius and thymus appear atrophic and yellowish in color as early as 4–6 dpi. Atrophy of bursa and thymus might be reversible after infection with low virulence virus, but

these lesions persist after infection with highly virulent MDV. The spleen is enlarged and in many cases marbled at 4–6 dpi. After infection with highly infected MDV, necrotic abscess can be observed not only in the spleen but also in other tissues (i.e., liver) at approximately 7–10 dpi (Witter *et al.*, 1980). Necrosis in lymphoid organs is more evident when 1-day-old susceptible chickens are inoculated with highly virulent MDV (early mortality syndrome).

Microscopic lesions

The productive infection in lymphoid organs reaches a peak at 5–6 dpi and is accompanied by cytolysis of lymphocytes and other cells, a hyperplasia of reticulum cells, accumulation of macrophages, and infiltration by granulocytes. In the thymus, the cytolytic infection and hyperplasia of reticulum cells occur mainly in the medulla, and the cortex is markedly regressed. Similar changes occur in the bursa, with destruction of the normal architecture. When regression of the bursa and thymus is not reversible, connective tissue replaces the main parenchyma and there is luminal lining epithelial infolding or undulation.

Antigen expression

Early cytolytic infection in lymphoid organs is characterized by the production of abundant viral antigen, as can be detected by a variety of techniques. Most of the antigens in the bursa and thymus can be detected in the medullary areas where necrosis is evident.

Transient paralysis

Clinical signs

As for lymphodegenerative syndromes, TP occurs only in unvaccinated chickens without maternal antibodies. In field conditions, TP was described in young pullets (8–18-week-olds) before the widespread use of vaccines (Zander, 1959; Cho *et al.*, 1970; Kenzy *et al.*, 1973). In those countries where vaccination of broilers is not a common practice, TP can be a problem in broilers chickens (30–40-day-olds) (Gimeno *et al.*, 1996). Clinically, TP is characterized by the development, 8–12 days following infection with an oncogenic MDV (Zander, 1959; Cho *et al.*, 1970; Kenzy *et al.*, 1973) of a flaccid paralysis that initially affects neck muscles and later tends to become generalized. The onset of TP is very abrupt and most chickens with TP recover completely within 24–48 h. An acute form of TP occurs after infection with highly virulent MDV (Witter *et al.*, 1999). In acute TP, most chickens die within 24–48 h.

Gross lesions

TP is not associated with any gross lesions. However, most of the chickens suffering TP have bursa of Fabricius and thymus atrophy because of concomitant lymphodegenerative syndromes.

Microscopic lesions

The development of vasogenic edema subsequent to vasculitis is the lesion responsible for the establishment of TP. Several chronological studies of the changes occurring in the brain after MDV infection have been conducted (Gimeno *et al.*, 2001; Swayne *et al.*, 1989). Endothelial cells of the brain capillaries are among the first altered element in the brain of infected chickens. As early as 6–8 dpi, endothelial cells become hypertrophic and hyperplastic (Gimeno *et al.*, 2001). Following these early alterations, macrophages and lymphocytes cross the blood–brain barrier, forming perivascular cuffing and extending into the neuropil. Reactivation of the infection in some of the infiltrative lymphocytes has been associated with the development of vasculitis characterized by severe damage and infiltration of heterophils in the vascular wall. Leakage of immunoglobulin G and albumin around affected vessels result in vacuolization. The edema and vasculitis is expressed coordinately with clinical flaccid paralysis and resolved in 2–3 days. Other brain lesions (perivascular cuffing, lymphocytosis, and gliosis) can be detected after recovery of TP or in MDV-infected by clinically normal chickens (Swayne *et al.*, 1989).

Antigen expression

MDV antigen expression can be detected in the brain as early as 6 dpi. Replication of MDV seems to be incomplete as early antigens (i.e., pp38 and meq) but not late antigens (gB) are expressed. Time course and level of expression of MDV antigens are related with the establishment of brain lesions and development of TP.

Panophthalmitis (Gray eye)

Clinical signs

Birds with ocular involvement may show evidence of blindness (Ficken *et al.*, 1991); (Pappenheimer *et al.*, 1929; Spencer *et al.*, 1992). The blindness can be uni- or bilateral, although recognition of clinical blindness requires careful observation and is usually overlooked in the field. Affected eyes gradually lose their ability to accommodate to light intensity.

Gross lesions

Gross ocular changes, including the loss of pigmentation in the iris ('gray eye') and irregularity of the pupil, are caused by mononuclear infiltration of the iris. Cataracts; conjunctivitis, occasionally with multifocal hemorrhages; and corneal edema have also been observed (Ficken *et al.*, 1991).

Microscopic lesions

Pandiri *et al.* (2008) classified MDV-induced lesions in the eye as early lesions (6–11 days postinoculation, dpi) and late lesions (26 and 56 dpi) based on the location and severity of the lesions. The early lesions involved iris, ciliary body, and choroid layer and are characterized by endothelial cell hypertrophy, vasculitis, and infiltration of lymphocytes (mainly CD8 +), plasma cells, macrophages, and heterophils. Late lesions consisted of severe lymphohistiocytic uveitis, keratitis, pectenitis, vitreitis, retinitis, and segmental to diffuse retinal necrosis.

Antigen expression

Pandiri *et al.* reported expression of MDV antigen pp38 in the cells infiltrating choroid layer at 11 dpi and within the retina, uveal tract, and corneal epithelium during later stages of infection (Pandiri *et al.*, 2008). No expression of late antigen gB or oncoprotein *meq* was detected, which rules out the possibility that infiltrated cells were transformed.

Inflammatory lesions in various organs related to Marek's disease virus infection

MDV induces inflammatory and degenerative lesions in various organs that do not get accompanied by the development of clinical signs and that might or might not develop into neoplastic lesions. It is important to differentiate between those inflammatory lesions (indication of MDV infection) and proliferative lesions (indication of MD).

- Inflammatory lesions in the brain are not always related to the development of TP. Perivascular mononuclear infiltration (perivascular cuffing), gliosis, and astrocytosis are common findings in MDV-infected chickens regardless of the onset of TP. These lesions appear as early as 6 dpi and in most cases persist.
- Inflammatory lesions in the nerves can occur as early as 6 dpi. They are not associated with the development of clinical signs and often occur in the absence of gross enlargement of nerves. Pathogenesis and nature of inflammatory nerve lesions are very similar to the ones described in the brain for TP. The development of nerve lesions have been studied chronologically (Lawn and Payne, 1980). Initial lesions include mainly perivascular cuffing composed of macrophages and small lymphocytes and occur as early as 6 dpi. Sometimes vasculitis occurs and severe damage of the blood vessel wall is observed. In severe cases, lymphocyte infiltration is not only restricted to perivascular location but can also affect the neuropil. Mild inflammatory lesions in the nerves can be induced by all three MDV serotypes and can regress without inducing clinical signs. However, when these lesions are induced by an oncogenic virus, they might progress to the development of lymphomas.
- MDV-induced lymphoid infiltration and inflammatory lesions occur in a variety of other visceral organs and tissues during the second cytolytic infection. These lesions are not associated with any clinical manifestation. However, it is important to differentiate those inflammatory lesions that only indicate infection with MDV from neoplastic lesions that determine the development of disease. Also, mild inflammatory lesions in many tissues can also be induced by a variety of infectious and noninfectious agents. Under field conditions, it is very difficult to associate these lesions with MDV infection.
- Early lesions in the skin are not normally associated with clinical signs or gross enlarged follicles and in general have to be identified by microscopic analysis. They are important as they seem to be necessary for the infection of the FFE and therefore for the transmission of the disease. Early pathological changes in the skin can be classified as inflammatory (perifolliculitis and inflammatory infiltration in the feather pulp) and degenerative due to the replication of MDV in the FFE. Inflammatory lesions in the dermis and in the feather pulp can either regress or progress to the development of tumors. Chronological studies have shown that lesions in the feather pulp resemble those in the nerves (Cho *et al.*, 1998).

Vascular syndromes (Arteriosclerosis)

Experimentally, infection with MDV has been associated with increased rates of arteriosclerosis (Fabricant *et al.*, 1978). However, the development of arteriosclerosis is a multifactorial phenomenon and the practical relevance of arteriosclerosis induced by MDV is not clearly determined. It, however, seems unlikely that MDV-induced arteriosclerosis has an important impact in the poultry industry because vaccination with turkey herpesvirus protects chickens against it (Fabricant *et al.*, 1981). No clinical signs have been associated with MDV-induced arteriosclerosis.

Diagnosis and Differential Diagnosis

MDV is ubiquitous and under field conditions, most, if not all, chickens are infected with oncogenic MDVs regardless of their vaccination status. Most of them, however, are properly protected by vaccination and never develop MD or any of the other syndromes induced by MDV. Therefore, detection of MDV by itself cannot be used for diagnosis of MD or any of the other MDV-induced syndromes.

This section focuses mainly on the diagnosis of MD and the differential diagnosis with other poultry tumor diseases. Diagnosis of nonneoplastic syndromes induced by MDV is presented at the end of the section.

Diagnosis of Marek's Disease (Neoplasia) and Differential Diagnosis with Other Poultry Viral Tumor Diseases

The diagnosis of lymphomas is fundamentally different from the diagnosis of many other diseases of chickens and presents numerous challenges to the diagnostician. Three distinct viruses can induce lymphoma in poultry: one herpesvirus (MDV) and two retroviruses (Avian leukosis virus (ALV) and reticuloendotheliosis virus (REV)). Lymphomas induced by the three viruses appear similar on superficial inspection because, by definition, they are all composed of lymphocytes. Although organ and tissue tropisms differ, there is no truly pathognomonic lesion for any of the lymphoma types. Each virus can induce tumors in many different tissues. In the case of ALV and REV, two different viruses can induce identical bursal lymphomas that, in all important respects, constitute the same disease. Perhaps the most confusing issue is the high probability of multiple infections. The three virus types are each widespread in nature and, once infection occurs, may reside in infected chickens for long periods. Moreover, most infected chickens never develop tumors. In some retroviral lymphomas, the fully infectious form of the causative virus disappears. Thus, the presence of the virus does not necessarily indicate the presence of the disease, and in some cases the disease can be present in the absence of the virus. A review of differential diagnosis of poultry tumor diseases has been recently published (Witter *et al.*, 2010) and readers are encouraged to read it for further details.

The diagnosis of MD is a multistep process. The tentative diagnosis can be done in the farm and includes the evaluation of epidemiological, clinical, and pathological parameters. Confirmation of the diagnosis in the laboratory could be done by histopathology, immunohistochemistry, and real-time polymerase chain reaction (PCR). **Table 3** summarizes the

Table 3 Differential diagnosis of tumor viral diseases in poultry

Age (weeks)	*Gross lesions*	*Differential diagnosis*	*Test to confirm diagnosis*	
			Aid in the diagnosis	*Confirm diagnosis*
<14	Enlarged nerves	Marek's disease Peripheral neuropathy	Histopathology	Real-time polymerase chain reaction (PCR)
	Tumors in viscera + enlarged nerves	Marek's disease	Not necessary in most cases	Not necessary in most cases
	Tumors in viscera	Marek's disease Acutely transformed retrovirus	Histopathology Immunohistochemistry	Real-time PCR
>14	Enlarged nerves	Marek's disease Peripheral neuropathy Reticuloendotheliosis (neuritis)	Histopathology	Real-time PCR
	Tumors in viscera + enlarged nerves	Marek's disease Reticuloendotheliosis virus (REV)-induced tumors	Histopathology Immunohistochemistry	Real-time PCR
	Tumors in viscera	Marek's disease Avian leukosis virus (ALV)-induced tumors REV-induced tumors	Histopathology Immunohistochemistry	Real-time PCR
	Tumors in the Bursa of Fabricius	Marek's disease ALV-induced tumors REV-induced tumors	Histopathology Immunohistochemistry	Real-time PCR

main differential diagnosis to consider and the necessary test to confirm a diagnosis.

Tentative diagnosis

Epidemiology

Age has been used traditionally as a criterion to differentiate MD from retrovirus-induced tumors. Both REV and ALV requires longer time to transform lymphocytes than MDV. Therefore, if a chicken younger than 14 weeks develops lymphomas, MDV is the most likely etiology. However, MDV is able to induce tumors in young as well as old chickens; hence, this criterion has its own limitations.

Clinical signs

Retrovirus does not induce specific clinical signs. Chickens with retrovirus-induced tumors develop nonspecific signs, such as depression, lethargy, ruffled feathers, etc. MDV can affect the brain and peripheral nerves and if tumors develop on those tissues, chickens will develop neurological clinical signs (paralysis, ataxia, tremors, torticollis, etc.). However, if MDV-induced lymphomas are not affecting nervous system, clinical signs will be nonspecific, just like those induced by retroviruses.

Gross pathology

Involvement of the peripheral nerves is normally associated with MDV-induced lymphomas. If peripheral nerve enlargement is present, MDV is the most likely cause of the tumors. However, this assumption has two limitations. Peripheral neuropathy (PN) syndrome is a nonneoplastic syndrome that induces enlargement of peripheral nerves just like MDV does (Bacon *et al.*, 2001b; Witter *et al.*, 2010). In the absence of visceral tumors and if only nerve lesions are present, further diagnostic tests have to be done to differentiate between MD and PN. If there are both nerve and visceral tumors, PN is ruled out. However, REV can induce lymphoma in viscera and neuritis that could easily be confused with MD. In this case, further diagnostic tests are needed.

- Detection of bursal tumors is a common feature in tumors induced by retroviruses (both ALV and REV). However, they are not presented in all chickens with retrovirus-induced tumors. Also, MDV can induce bursal tumors that grossly look identical to those induced by retroviruses.
- Eye lesions have been used as criterion to diagnose MD because retrovirus does not affect eyes. As mentioned in other sections of this article, MDV-induced eye lesions are not neoplastic in nature and therefore are only indicative that those chickens are infected with MDV.
- Skin lesions, especially in meat-type chicken, are more common in chickens with MD than in chickens with retrovirus-induced tumors. Nonetheless, if only skin lesions are present, it is necessary to differentiate between MDV-induced skin lesions and other skin lesions, such as squamous cell carcinoma and inflammation due to infectious agents and ectoparasites.

Laboratory diagnosis

1. Histopathology: Samples of tumors and peripheral nerves of animals freshly killed should be collected and fixed in buffered formalin at 10% for an adequate histopathological evaluation. Two criteria are evaluated by histopathologists – distribution of lesions and characteristics of the tumor cells.
   a. Distributions of the lesions:
      - Lymphomas in visceral organs accompanied with lymphoma in nerves. Those lesions are characteristics of MD and diagnosis can be confirmed by histopathology. However, it is important to confirm that nerve lesions are indeed neoplastic (Type A) and not

inflammatory. Inflammatory lesions in the nerves are an indication of infection but not of MD.
- Lymphomas only in nerves. In this case, the diagnosis of MD can be done by histopathology if lesions are type A. If lesions are type B, it is necessary to differentiate between MD and PN by other methods.
- Lymphomas only in viscera. Those lesions could be due to retrovirus or to MDV, and further tests are needed.
- Lymphomas in the bursa. This lesion can be very helpful in the diagnosis by histopathology. Retrovirus-induced tumors induce intrafollicular lymphomas. MDV induces extrafollicular lymphomas.

b. Tumor cells morphology can also aid in the diagnosis if samples were collected from animal freshly killed and fixed properly. ALV-induced lymphomas are formed by homogeneous population of lymphoblast, whereas MDV-induced lymphomas are formed by a heterogeneous population of cells, including large, medium, and small lymphocytes and macrophages. REV-induced lymphoma normally are identical to those induced by ALV but sometimes can be very similar to those induced by MDV.

One of the major challenges in the diagnosis of MD by histopathology is the differentiation between inflammatory lesions induced by MDV and development of lymphomas also induced by MDV. First, MDV is the etiology of both kinds of lesions. Also, inflammatory lesions can progress to the development of neoplastic lesions, but this is not always the case. Finally, lymphomas are composed by a mixture of neoplastic and inflammatory cells. It is a fact that inflammatory lesions not always lead to the development of lymphomas and that even MDV vaccines (i.e., HVT) can induce them (Witter *et al.*, 1976). Interpretation of borderline inflammatory/neoplastic lesions has to be done carefully based on other evidence of the disease (i.e., clinical signs, gross lymphomas, etc.). In many cases, further diagnostic tests are necessary to differentiate between inflammation and MDV-induced tumors.

2. Immunohistochemistry: Characterization of the phenotype of tumor cells by immunohistochemistry can be very useful in the differential diagnosis of poultry tumor diseases. MD tumors are composed of T cells, whereas ALV-induced lymphomas are composed of B cells. REV tumors are generally composed of B cells, but sometimes they can be T cells instead. The major drawback of phenotypic characterization of tumor cells is that most commercially available antibodies against chicken's antigens do not work very well in formalin-fixed samples; moreover, samples have to be snap frozen in liquid nitrogen.
   a. Detection of oncogene meq in tumor cells by immunohistochemistry is another option more specific than identification of cell phenotype (Gimeno *et al.*, 2005). MD-induced tumor cells express high levels of meq, but this is not present in retrovirus-induced tumors or in PN lesions. The limitation of this technique, however, is that antibodies against meq are not commercially available.
   b. Expression of other cell markers, such as MATSA and AV37, is high in MD tumors (Gimeno *et al.*, 2005). However, they are not specific and can also be present in other tumors or even in inflammatory lesions (Gimeno *et al.*, 2005; Schat and Calnek, 1978b). Therefore, its use in diagnostic is limited.
3. Real-time PCR: Quantification of the MDV DNA by real-time PCR is highly useful for confirmation of MD tumors, because tumorous tissue contains 100-fold higher levels of MDV DNA than latently infected tissue (Gimeno *et al.*, 2005). The same assay can be used for early diagnosis as early as 3 weeks of age (Gimeno *et al.*, 2008). Quantification can be done by using a standard curve (absolute quantification) or by the Ct method (relative quantification). However, the Ct method (relative quantification) is recommended as it is easier to standardize at different laboratories and does not require the use of a standard curve. Diagnosis of MD can be done using tumors, blood, and feather pulp (Cortes *et al.*, 2011). Samples can be stored frozen at $-70\ ^{\circ}C$ or can be collected in Flinders Technology Associates (FTA) cards (Cortes *et al.*, 2009). The latter has several advantages for storing and shipping.

Diagnosis of Nonneoplastic Syndromes

1. Lymphodegenerative syndromes: Diagnosis of lymphodegenerative syndromes in the field is very difficult. Besides MDV, a variety of other diseases of infectious (infectious bursal disease, chicken infectious anemia, etc.) and noninfectious (aflatoxins and stress) etiology induce necrosis and atrophy of the lymphoid organs. Moreover, expression of MDV antigens is very high during the peak of the productive infection (5–6 dpi) but is transient and often no MDV antigens can be detected in atrophied lymphoid organs. An important point to consider is that lymphodegenerative syndromes do not occur in MDV-vaccinated chickens or in chickens bearing maternal antibodies against MDV.
2. TP: Diagnosis of TP can be made in most cases by the characteristic clinical signs. Healthy chickens suddenly develop flaccid neck paralysis that become generalized and in a short time (24–48 h) either recover or die. TP appears only in unvaccinated chickens that lack maternal antibodies against MDV. In field cases, TP has been diagnosed in unvaccinated flocks of broilers at 3–4 weeks of age, when maternal antibodies have disappeared. Evaluation of the microscopic lesions in the brain can confirm the existence of vasculitis and brain edema. Detection of MDV DNA in the brain is not an adequate method of diagnosis for TP as it can also be detected in infected chickens without TP (Witter *et al.*, 1999). TP has to be differentiated from other diseases producing paralysis (i.e., botulism and peripheral neuropathy) and brain lesions (i.e., Newcastle disease, avian influenza, west Nile virus, encephalomalacia, encephalomyelitis, toxoplasmosis, and bacterial encephalitis). Both TP and botulism produce flaccid paralysis, but no brain lesions can be found in botulism. Peripheral neuropathy is characterized by the enlargement of peripheral nerves, which is not present in chickens with TP. Brain lesions induced by other viral encephalitis (Newcastle disease, avian influenza, west Nile virus, and encephalomyelitis) could be confused with those induced

by MDV in chickens with TP. The transient nature of TP aids in the diagnosis. In addition, in the other viral encephalitis, neurons are affected, but this is not the case for TP. Finally, vascular lesions in TP are slightly different because along with the endotheliosis and perivascular cuffing (common with the other viral encephalitis) there is severe vasculitis and brain edema. Toxoplasma, bacterial encephalitis, and encephalomalacia are characterized by severe infiltration of heterophils, necrosis, and in the case of encephalomalacia thrombosis. None of these lesions are detected in chickens with TP. Finally, it is important to differentiate TP lesions from other MDV-induced lesions in the brain that are not related with the development of TP. Perivascular cuffing, gliosis, and lymphocytosis can occur at the same time as the development of TP but are not related with the development of the syndrome (Swayne *et al.*, 1989).

3. Immunosuppression: MDV-IS is very complex and other than atrophy of lymphoid organs, at the moment, there is no any method to diagnose MDV-IS. Further studies are warranted for better understanding of MDV-IS, methods of detection, and methods of control.

Control

Control of Marek's Disease

MD control is based on three criteria: good biosecurity, selection for genetic resistance, and vaccination. Biosecurity and genetic resistance are currently used as important adjuncts to vaccination rather than as primary control strategies. The focus of this article is mainly on vaccines and vaccination protocols. Recent reviews on MD vaccines and control procedures are available for further details (Bublot and Sharma, 2004; Gimeno, 2008; Schat and Baranowski, 2007).

Genetics

The relevance of genetic resistance in the control of MD was observed several decades ago (Cole, 1968) and indeed was the first method for controlling the disease. Primary breeder companies frequently include MD resistance as one of the criteria for selection. The strategies to select MD resistance have been reviewed (Bacon *et al.*, 2001a) and include mainly mass selection (i.e., breeding from survivors) and family selection utilizing pedigreed offspring as breeders. There are two groups of genes in the chicken that influence MD resistance: MHC genes and non-MHC genes. The relevance of MHC genes in MD resistance has been amply demonstrated (Bacon *et al.*, 2001a) and is well characterized. Particularly remarkable is the influence that the B haplotype has on the efficacy of MD vaccines and how this influence depends on the serotype of the vaccine (Bacon and Witter, 1992, 1994a,b). Theoretically, one could select the most appropriate vaccine based on the predominant B haplotype of a particular strain. This issue has not been exploited in the practice because of the difficulties in determining the predominant B haplotype, especially in meat-type chickens. However, it is now technically possible to identify the predominant B haplotype in meat-type chickens, and as molecular techniques improve it might be economically feasible for commercial lines (Li *et al.*, 1997; Goto *et al.*, 2002).

Several non-MHC genes may also be involved in resistance. For example, line 6 and line 7 chickens differ markedly in MD susceptibility, but both lines are homozygous for the MHC B^2 allele (Crittenden *et al.*, 1972). Numerous studies have identified and mapped several quantitative trait loci (QTL) (Bumstead, 1998; Vallejo *et al.*, 1998; Xu *et al.*, 2011). The studies are still ongoing but the rapid technological advances in complete genome sequencing and single-nucleotide polymorphism analysis will identify several specific genes associated with resistance to MD.

Biosecurity

Taking the example of specific pathogen-free flocks, MD can be eradicated from a farm if ideal conditions of biosecurity are followed. Unfortunately, the use of filtered air and positive pressure housing is not economically feasible for the poultry industry. However, a proper biosecurity plan will be of great help for controlling MD. There are two critical points that any biosecurity plan should consider: Reduce initial levels of MDV in the farm by preventing entry of MDV into the building and avoid contamination of the environment by preventing MDV from leaving the building. Measures to reduce initial levels (all in–all out systems, single-age buildings, etc.) of MDV have been widely stressed, although not always followed. Measures to avoid contamination of the environment, however, are not always well recognized and there are two issues that deserve more attention: air management and disposal of chicken carcasses and manure. Biofilters designed to remove odors from air emanating from livestock facilities might be a solution to decrease the level of MDV contamination in the air exiting poultry farms (Spencer and Guan, 2004). Carcasses are usually burned or buried, but disposal of manure does not normally receive the attention it requires. Composting has been shown to be a satisfactory alternative procedure for discarding both carcasses and manure (Spencer and Guan, 2004).

Vaccination

Vaccination protocols

- Types of vaccines
  Modified live vaccines are the cornerstone for protecting against MD. There is a large selection of licensed MD vaccines representing three MDV serotypes. In general, three types of formulation in ascending order of efficacy are as follows: HVT alone, HVT plus a serotype 2 strain, and CVI988 (Rispens) with or without viruses of serotypes 2 and 3. A decade ago, a novel serotype 1 MDV vaccine (strain BH16) was introduced in Australia and seems to confer at least as much protection as CVI988 (Karpathy *et al.*, 2003; Karpathy *et al.*, 2002). Recently, several recombinant vaccines using HVT as a vector have become available and are widely used alone (mainly in broiler chickens) or in combination with vaccines of serotypes 1 and 2. In addition, recombinant vaccines using serotype 1 strains (either as a vector expressing other viruses' genes or by deleting complete or partially the oncogene meq) have been developed and are still under experimental evaluation

(Zelnik *et al.*, 1995; Morgan *et al.*; 1998; Cui *et al.*, 2005; Lupiani *et al.*, 2004).

MDV is highly cell associated and as a result, vaccines are produced in chick embryo cells, stored in liquid nitrogen, and administered as viable cell suspension. HVT, although not serotypes 1 and 2 MDV, can be produced as a cell-free suspension and stored in a lyophilized state. However, the cell-associated form of HVT vaccine has been most widely used because it is more effective than cell-free virus in the presence of maternal antibodies.

- Vaccine administration
  Early immunity is essential because most chicks face challenge from MDV within a few days of being introduced into their brooding pens. Therefore, MD vaccines are administered to chicks at hatch by subcutaneous or intramuscular inoculation or *in ovo* at ED18 via amniotic or intraembryonic route (Sharma and Burmester, 1982). Cell-associated vaccines are very labile. Only viable infected cells are capable of transmitting the vaccine virus, so handling is of crucial importance for a vaccine to retain its efficacy (Halvorson and Mitchell, 1979). Failures in the cold chain (MD vaccines have to be kept in liquid nitrogen and maintained under refrigeration), improper thawing conditions, and reconstitution in inadequate diluents can severely reduce vaccine titers. Other factors such as mixing with antibiotics (Colwell *et al.*, 1975; Eidson *et al.*, 1978), joint administration with other vaccines (Rosenberger, 1983), or long delays in vaccination after reconstitution can also decrease vaccine titers. Finally, dilution of vaccines to reduce vaccination cost is a common practice worldwide, especially in the broiler chicken industry. The negative effects of administered suboptimal doses of vaccine have been recently reported (Gimeno *et al.*, 2011a).

  Besides suboptimal vaccine dose, there are other factors that influence the efficacy of vaccines, such as early challenge with MDV before vaccine-induced immunity has been elicited; decreased immune competence of the chicken by either infectious or noninfectious causes; and presence of highly virulent viruses.

- There are three strategies (protective synergism, revaccination, and the use of adjuvants) that are commonly used to augment vaccine efficacy:
  1. Protective synergism: Combination of the SB1 strain (serotype 2) and the FC126 strain (serotype 3, HVT) provides better protection than either vaccine alone (Schat *et al.*, 1982; Witter, 1982). This phenomenon, termed protective synergism, is the basis for the bivalent vaccines developed in the 1980s. Synergism is strongly serotype-specific and is especially evident between combinations of serotypes 2 and 3 (Witter, 1992). No protective synergism has been reported between combinations of serotype 1 with serotypes 2 or 3. However, augmentation of protection for MD vaccines has been observed with two additional systems. Combinations of HVT and glutaraldehyde-inactivated serotype 1 MDV obtained from feather follicles was reported to improve protection (Pruthi *et al.*, 1987). Combinations of HVT and a recombinant fowlpox virus expressing gB and other glycoproteins of serotype 1 MDV also provided improved protection (Nazerian *et al.*, 1996). The mechanisms involved are poorly understood and represent an overlooked but important area for future research.
  2. Double vaccination: The practice of administering MD vaccine a second time has been used in commercial poultry flocks for many years. It became popular in the United Kingdom and was adopted by many growers in Europe and other countries but has not been common in the United States. The author has recently conducted several experiments to develop a model that allows to reproduce the benefits for the second vaccination under laboratory conditions. Her results indicate that the benefit of double vaccination can be achieved by using a less efficient first vaccine followed by a more efficient second vaccine (Gimeno *et al.*, 2011b). *In ovo* vaccination followed by a second vaccination at the day of age seems to be the most beneficial protocol (Gimeno *et al.*, 2011b). An early and strong activation of T cells following the *in ovo* vaccination has been suggested to be, at least partially, responsible for the benefits of double vaccination (Gimeno *et al.*, 2012).
  3. Use of adjuvants and immunomodulators: MD vaccines are administered in embryo or in 1-day-old chicks. The use of immunomodulators, such as cytokines and adjuvants, along with MD vaccines could enhance the innate immune response and induce an earlier maturation of the immune systems of the chickens. Acemannan, a polysaccharide, has been licensed as an adjuvant of MD vaccines in the US since 1992 but is not widely used. Several studies have been conducted to include cytokines in MD vaccines to enhance the cellular immune response (Djeraba *et al.*, 2002; Tarpey *et al.*, 2007). This area of research will continue in the future and may be a solution to increase the protection conferred by current vaccines.

- Monitoring vaccination
  Because of its cell-associated nature, MD vaccines are labile and failures in the administration might occur. Monitoring replication of the vaccines in the chicken can ensure that vaccination was correctly administered. Evaluation of MD vaccines in the chickens has been traditionally done by plaque assay (Cho, 1981). Recently, primers specific for each MD serotype have been designed and real-time PCR has slowly overtaken the traditional plaque assay. It has been recently demonstrated that feather pulp is an adequate sample to monitor MD vaccination for vaccines of all three serotypes (Cortes *et al.*, 2011; Baigent *et al.*, 2005). Spleen can also be used, but that requires euthanizing animals. The use of blood is not advisable due to the high numbers of false negative (Cortes *et al.*, 2011). Sample can be taken fresh and stored frozen until processed or in FTA cards (Cortes *et al.*, 2009). The latter has the advantage of an easy storage and shipping. It is recommended to sample chickens between 1 and 3 weeks of age to monitor how vaccine was administered. After 3 weeks of age, the levels of MD vaccines achieve a plateau even if very low dose of vaccine was administered (Gimeno *et al.*, 2011a; Baigent *et al.*, 2007).

Control of Nonneoplastic Syndromes

Development of lymphodegenerative syndromes, TP, and arteriosclerosis is severely limited or abolished by vaccination with HVT regardless of the virulence of the challenged MDV strain. Control of MDV-IS is uncertain. Recent studies have demonstrated that vaccination (albeit able to control the development of MD) does not protect completely against the permanent immunosuppression induced by MDV. Further studies on the mechanisms behind MDV-IS are warranted to develop better methods to detect and control it.

Glossary

Agricultural intensification The increase of yield (i.e., amount of commodity produced per unit area) in agricultural areas through increased inputs of labor, fertilizer, pesticides, etc.

Certification The programs in which farmers contract third-party certifiers to confirm their adherence to specific production criteria, with the cost of certification outweighed by the ability to sell agricultural products at a price premium to consumers.

Ecosystem services The direct and indirect benefits of natural ecosystems for human livelihoods; these are also known as environmental services.

Market externalities A cost or benefit of the production or sale of a product that affects other parties not involved in the transaction and that is not generally reflected in the cost of the product.

Market failure In the context of ecosystem services, when the prices of goods and services do not reflect their true costs of production or consumption (e.g., the true cost of fossil fuel production with respect to impacts on global climate is not reflected in its cost, resulting in environmental degradation).

Nonexcludable service An ecosystem service that a beneficiary will receive regardless of whether or not they compensate the provider (i.e., there is no way to exclude those who do not pay providers for the service).

Opportunity costs The financial benefits that are foregone by making one choice over another (e.g., the potential revenue lost by choosing to grow crops in less productive manner that is more likely to maintain ecosystem services).

Payments for environmental services The voluntary agreements between purchases and sellers by which the beneficiaries of ecosystem services pay those who produce or manage such services in order to incentivize their protection and maintenance.

Shade coffee The practice of growing coffee under a canopy of native or introduced trees to shield the plants from excessive sunlight.

Technification of coffee The process of reducing or eliminating shade cover and at the same time increasing the density of coffee plants; initially promoted by the United States Agency for International Development in the 1970s as a method to reduce impact of coffee leaf rust.

Introduction

Virtually all aspects of human livelihoods and well-being are dependent on the resources and processes provided by natural ecosystems. Known as 'ecosystem services' or 'environmental services,' these are the direct and indirect benefits of natural resources and ecosystem processes for human economies (Millennium Ecosystem Assessment, 2005). Environmental services encompass a diverse range of products and processes, from carbon cycling to cultural and spiritual renewal (**Figure 1**). In addition to providing tangible or intangible benefits for human societies, the majority of environmental services share another characteristic: they are positive externalities, providing a net benefit to society whose value is not reflected in the cost of the direct products and services affected (Polasky, 2012; Salzman, 2009). The positive externalities of environmental services provide an example of market failure (Salzman, 2009); spontaneously arising markets fail to reflect the true value of these services, leaving them vulnerable to overexploitation and degradation.

Agricultural production is itself a provisioning service (Zhang *et al.*, 2007) reliant on a diverse suite of ecosystem services operating at a variety of spatial and temporal scales (Kremen and Miles, 2012). Given that agricultural production comprises approximately 40% of land cover (Foley *et al.*, 2005), managing agriculture in order to maximize the provision of ecosystem services, while minimizing disservices (e.g., soil degradation and pesticide contamination), is a key component of moving toward sustainability in the twenty-first century (Robertson and Swinton, 2005). Diversified agricultural systems are more effective in supporting ecosystem services and minimizing disservices (Kremen and Miles, 2012); however, low-diversity and high-intensity conventional systems have become the norm throughout the world. This situation results from interactions between local history, policy, lack of research, and market failures that compensate farmers for yields but not for positive (or negative) externalities involved in production. In this article, the authors have described relationships between agricultural management and ecosystem service provision for a single crop – coffee, the most important tropical agricultural commodity crop, which is responsible for US$15 billion in exports annually (International Coffee Organization, n.d.). Using this example, the attempts to incentivize biodiversity conservation and compensate producers for the production and maintenance of ecosystem services were investigated. To provide a broader context for this discussion, the article begins with a description of the currently existing market-based mechanisms for conservation in agricultural landscapes, highlighting the advantages and disadvantages of voluntary and regulatory approaches.

Framework of ecosystem services adapted from Millennium Ecosystem Assessment, 2005. Ecosystems and Human Wellbeing: A Framework for Assessment. Washington, DC: Island Press.

Market-Based Incentives: Promise and Pitfalls

Although the importance of ecosystem function for human well-being has long been acknowledged, the ecosystem services framework was first articulated in the 1970s and elaborated in the 1980s (Mooney and Ehrlich, 1997). The development of the service framework came about not necessarily due to the desire to explicitly value services, but rather as a response to the failure of conservation efforts based on appeals to nature's intrinsic value (Norgaard, 2010). Nevertheless, the ecosystem services framework provides a structure in which these functions can be valued and incentivized.

Existing market-based incentives exist along a continuum from entirely voluntary mechanisms to mechanisms dependent on regulatory interventions that integrate market externalities into economies (Figure 1). Commodity markets

(e.g., market for timber, agricultural products, etc.) are themselves dependent on provisioning services. However, for the purposes of this article, the focus is on markets for the various sustaining, regulating, and cultural services that comprise the market externalities whose conservation has not been captured by spontaneously arising markets.

Voluntary Mechanisms

Among existing voluntary mechanisms, certification schemes, which indirectly incentivize biodiversity conservation and maintenance of ecosystem services, are the most widely available and applied incentives. These market-based approaches that compensate producers for ecosystem services are widely considered effective at promoting conservation in agriculture, although there are few empirical examples of such markets (Kroeger and Casey, 2007). Producers generally participate in third-party certification schemes with the expectation of a price premium in exchange for compliance with international standards of quality and fairness in production. Dozens of certification schemes exist within the agricultural sector, including well-known examples, such as organic and fair-trade certifications. Although a few of these certifications focus specifically on conservation of biodiversity or ecosystem services, most include related environmental criteria that presumably benefit biodiversity and ecosystem function. For example, organic agriculture appears to have limited, but highly heterogeneous, benefits for biodiversity of certain taxa, such as birds, bats, and invertebrates, that provide regulating services of pest control within farms (Bengtsson *et al.*, 2005; Hole *et al.*, 2005; Fuller *et al.*, 2005).

Despite the widespread adoption of some certification programs, the approach presents many weaknesses in the context of conservation. Certification schemes themselves reflect a shift from compulsory to voluntary participation in market mechanisms for conservation (Hatanaka *et al.*, 2005), in that responsibility for monitoring of standards that has traditionally rested with government agencies is shifted to third-party certifiers; consumers are free to 'opt out' by purchasing less expensive (and less sustainably produced) commodities. A review of major agricultural certifications found that most standards fail to provide specific guidelines for targeting the protection of endangered species and none specifically seek to prevent habitat loss (UNEP-WCMC, 2011). Additionally, the cost of certification and the price are a major barrier for small and medium producers to participate in these schemes, thus excluding many producers in the developing tropics. Without wide adoption, the conservation value of certification schemes may be very limited (Gullison, 2003).

Policy-Driven Mechanisms

The ability to opt out of voluntary schemes, such as certifications, necessarily limits the impacts of these approaches in terms of conservation of biodiversity and ecosystem services. Higher impact approaches generally involve national or international governmental mechanisms that compel participation on the part of producers, consumers, or both. One emerging approach in these situations is direct payments for conservation (In some cases, voluntary direct payments are made to producers for the provision of ecosystem services, such as water and erosion control, but these payments generally take place locally and are not sold on a competitive market.). Direct payments for conservation outcomes may be the most efficient means to incentivize conservation of biodiversity (Ferraro and Kiss, 2002) and, by extension, ecosystem services. Direct payments in agriculture may be made to farmers and landowners who through sound management practices may demonstrate a contribution to environmental services, such as water cycling, pollination, and soil. Although a number of small-scale, voluntary payment agreements have arisen (Pagiola *et al.*, 2004), larger scale programs generally occur through government subsidies (based on taxes, grants, or a combination of these two) for conservation or through payments for certain ecosystem services (Pagiola, 2008).

Environmental markets – in which biodiversity conservation interventions or ecosystem services are themselves sold as commodities – are often hailed as the next frontier in conservation practice; however, in practice there are very few examples of functioning environmental markets. Given that these are markets attempting to commodify externalities that are public goods without clear ownership, such mechanisms are unlikely to develop in the absence of national or international regulations limiting use of a readily available public good. Kroeger and Casey (2007) outlined three main reasons for the small number of ecosystem service markets: (1) absence of low cost and easily applicable approaches to quantifying ecosystem service flows, (2) difficulties in estimating the economic value of ecosystem services, and (3) the nature of the ecosystem flows as a public good. Thus, existing environmental markets rely on governmental regulation that creates a demand for ecosystem services. For example, in the United States, mitigation banking for wetlands and endangered species habitat exists as a direct result of government oversight of the issuance of credits and the sale and trade of such to potential buyers wishing to offset negative impacts of development (Bayon, 2008). Similarly, mitigation markets for greenhouse gases exist as a result of state legislation in the United States and regional legislation in Europe, in which farmers and other land managers may apply published standards to cap or capture carbon, selling these credits on voluntary or regulated carbon markets. For example, under the State of California climate change legislation AB-32, agricultural producers are able to sell carbon offsets within the regulatory market through sequestration and 'additional' sequestration gained through biodiversity friendly practices, such as minimal tillage and the use of cover crops (Sumner and Rosen-Molina, 2010). Participation in environmental markets is currently limited because of a lack of regulatory pressure, but in the case of existing markets, it is limited because of high transactional costs due to monitoring. Thus, as with certification, these up-front costs may serve as barriers to the small and medium producers who comprise the majority of agriculturalists in the developing world.

As one of the world's most important agricultural commodities, coffee provides a valuable lens for exploring

relationships between conservation, commodification, and globalization. In the following sections of this article, the authors have described various methods of coffee cultivation, focusing on Latin America ('Coffee Cultivation in Latin America'); effects of coffee cultivation on biodiversity and ecosystem service provision ('Coffee, Biodiversity, and Ecosystem Services'); and the existing voluntary and regulatory market mechanisms that have been used to incentivize the conservation of ecosystem services in Latin American coffee cultivation ('Market Incentives to Conserve Ecosystem Services in Coffee'). The authors have focused on the strategies that have shown the most success for conservation of biodiversity and ecosystem services in this important tropical crop and have made suggestions for future directions in market-based methods to incentivize conservation in agricultural landscapes in the tropics.

Coffee Cultivation in Latin America: Management Practices, Biodiversity, and Ecosystem Function

Introduced to the New World in the early eighteenth century, coffee cultivation expanded throughout Latin America after countries in the region gained independence from Spanish and Portuguese rule in the 1820s and 1830s, respectively (Pendergrast, 1999). In 2010, coffee plantations comprised more than 5.2 million ha in Central and South America (nearly 4% of total crop area) with a production value exceeding US$5 billion annually (Food and Agriculture Organization of the United Nations, n.d.). Two coffee species are widely cultivated in the Neotropics: arabica (*Coffea arabica*), sought after for its superior flavor, which grows at middle elevations (600–1500 m); and robusta (*Coffea canephora*), used primarily for manufacture of instant coffee due to its harsh flavor and high caffeine levels, which grows below 800 m elevation (Jha *et al.*, 2011). The following discussion applies to arabica coffee, drawing primarily from Latin American examples.

Traditional Coffee Management

Within Latin America, coffee is notable not only for its economic and social importance but also for its variety of growing systems. These various management types can be ordered along a gradient of increasing intensification (Moguel and Toledo, 1999). As intensification increases in coffee systems, the diversity and complexity of tree cover decrease, and coffee plant density rises (**Figure 2**). Depending on a variety of factors (local climate, coffee variety, and use of chemical inputs), yield may also increase with intensification (Soto-Pinto *et al.*, 2000; Perfecto *et al.*, 2005).

As the descendent of an understory plant, coffee is a shade-tolerant species; in traditional coffee production systems, shade trees are maintained to shield the coffee plants from receiving too much direct sunlight. The simplest coffee management systems in Latin America essentially replace the understory of a forested area. Although trees may be thinned, the shade cover is comprised entirely of native species with a multistratum canopy structure (Moguel and Toledo, 1999; Philpott *et al.*, 2008a). These 'rustic' systems generally occur on small scales as part of indigenous management practices (Moguel and Toledo, 1999). More common among small-scale producers are polycultural systems in which coffee is cultivated alongside fruit and timber trees mixed with native forest tree species that provide relatively high-shade cover and a thinner, but still multistratum, tree canopy. In these multicropping systems, noncoffee products may comprise up to one-third of the value derived from a coffee agroforest (Rice, 2008). In addition to producing multiple value streams, these systems are relatively low input. Transitional between traditional and intensive coffee systems are 'commercial polycultures' (**Figure 2**), in which a shade canopy is still maintained over the coffee, but mostly comprised of reduced diversity of planted trees subject to pruning to regulate shade levels.

'Modernization' of the Coffee System

Traditional coffee cultivation escaped the post World War II 'green revolution' largely intact. However, in the 1970s, coffee cultivation in Latin America underwent a rapid process of modernization, with conversion into reduced shade canopies, high-yield coffee varieties, and an increase in chemical inputs and the density of coffee plants (Perfecto *et al.*, 1996; Perfecto and Armbrecht, 2003). This process of 'technification' in Latin America initially began as a response to the arrival of coffee leaf rust (*Hemileia vastatrix*), a devastating fungal disease of coffee. Reducing shade was initially seen as a way to reduce moisture, and hence the spore formation, of the fungus (Perfecto *et al.*, 1996). Supported by funding from the United States Agency for International Development, governments in Latin America implemented modernization programs of shade removal coupled with dense plantings of high-yield coffee varieties that respond well to direct sun and chemical inputs; by 1996, 40% of Latin America's coffee area had been modernized (Rice and Ward, 1996). As the coffee leaf rust has proven less devastating than initially anticipated, the motivation for adopting low-shade systems has shifted to increasing yields (Perfecto *et al.*, 1996).

Intensified coffee systems may include some shade (**Figure 2**), but the height and shade cover is greatly reduced. The shade trees themselves may be a near monoculture of fast-growing trees. In Latin America, these are commonly native nitrogen-fixing species (*Inga* spp. and *Erythrina* spp.), although exotics (e.g., *Grevillea robusta*) may also be used (Perfecto *et al.*, 1996; Jha *et al.*, 2011). These trees may be subject to substantial pollarding and removal of epiphytes to decrease shade cover. In sun coffee, the shade layer is eliminated altogether, with dense plantings of high-yield coffee. Despite the widespread belief that reduced shade increases coffee production, the actual relationship between shade and production on a per plant basis is highly variable and inconsistent across studies (Perfecto *et al.*, 2005). Intensive systems generally do produce more coffee per ha; however, it is unclear whether these increases result from increased planting densities, use of sun-tolerant varieties, or other aspects of management. Low- or no-shade systems generally require higher chemical and labor inputs (Jha *et al.*, 2011).

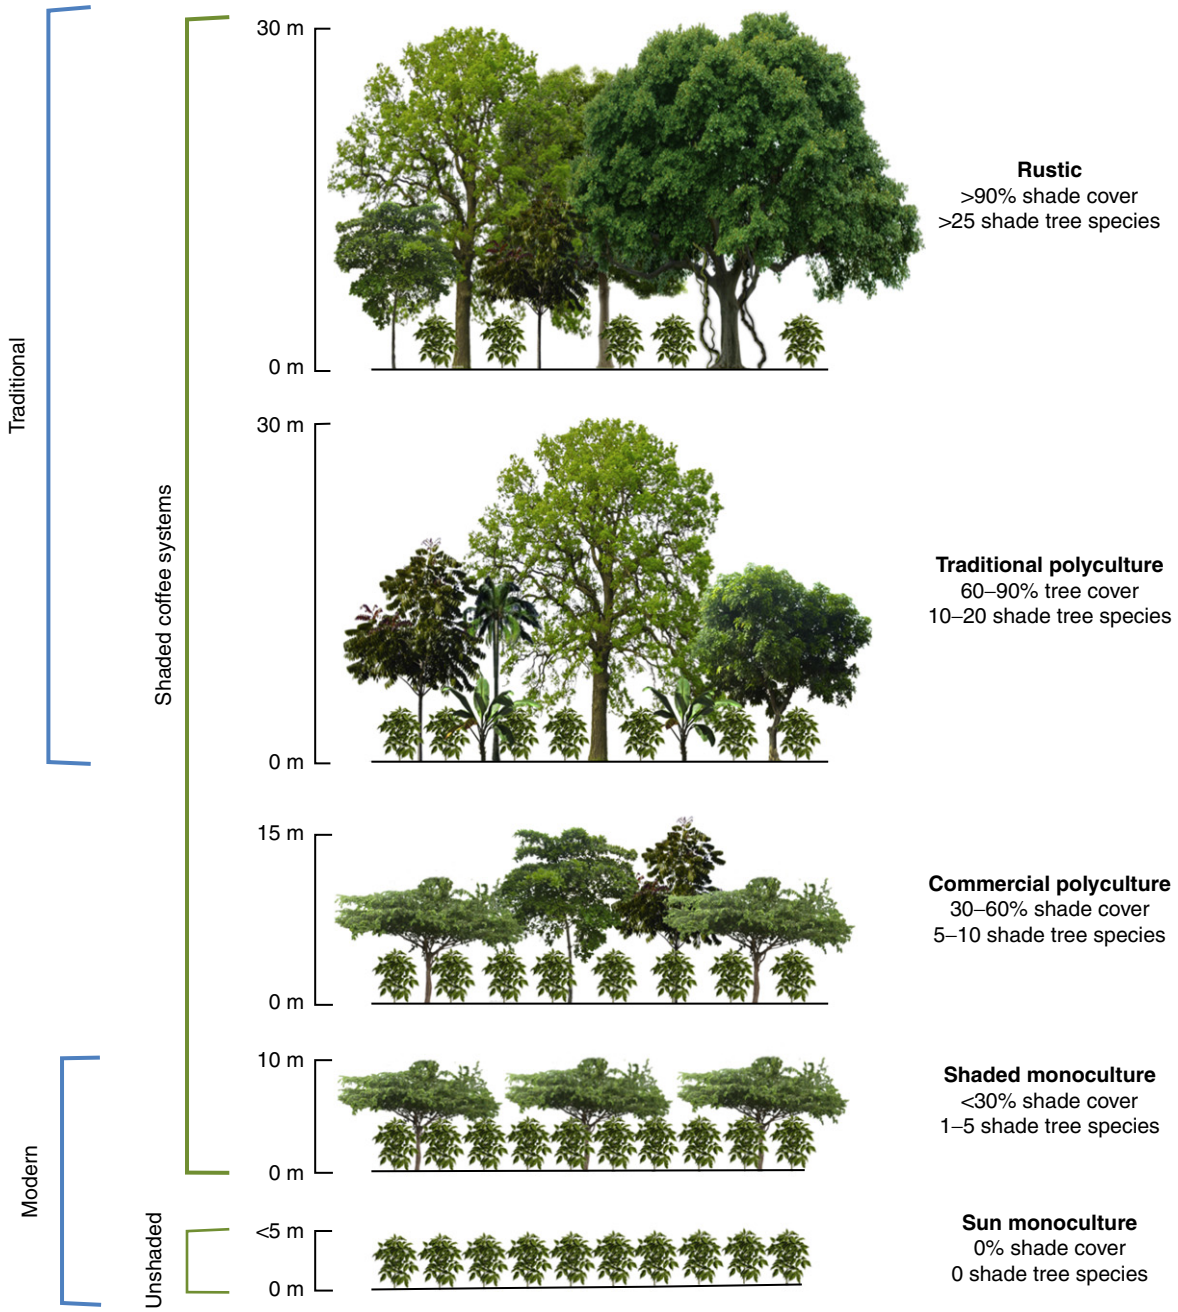

Figure 2 Schematic representation of coffee management systems from the least (top) to the most (bottom) intensive. As intensification increases, canopy height and structural complexity, tree basal area, and shade tree diversity decrease, whereas the density of coffee plants increases. Adapted from Moguel, P., Toledo, V., 1999. Biodiversity conservation in traditional coffee systems of Mexico. Conservation Biology 13(1), 11–21 and Perfecto, I., Vandermeer, J., Mas, A., Soto Pinto, L., 2005. Biodiversity, yield, and shade coffee certification. Ecological Economics 54 (4), 435–446.

Coffee Cultivation, Biodiversity, and Ecosystem Services

Biodiversity conservation in shade coffee plantations

Not surprisingly, these different coffee production systems vary not only in inputs (i.e., labor and agrochemicals) but also in their conservation value and their provision of ecosystem services. The maintenance of biodiversity is one of the most extensively studied ecosystem services provided by shaded coffee plantations (Perfecto *et al.*, 1996; Moguel and Toledo, 1999; Perfecto and Armbrecht, 2003; Donald, 2004; Somarriba *et al.*, 2004; Philpott *et al.*, 2008a).

By definition, traditional shaded coffee systems include a higher diversity of woody plants than modernized coffee plantations (Soto-Pinto *et al.*, 2001; Philpott *et al.*, 2008a; Williams-Linera and López-Gómez, 2008). Similarly, the epiphyte richness is higher in diverse shade coffee than in

intensive shade coffee and species numbers are similar between the most traditional systems and forests (Pendergrast, 1999; Hietz, 2005; Solis-Montero *et al.*, 2005; García-Franco, 2008). However, the richness and abundance of herbaceous understory plants may be substantially reduced as a result of coffee layer management (Saldaña-Vázquez and Sosa, 2010). Shaded coffee also facilitates bee-mediated pollen dispersal of native trees within coffee landscapes (Jha and Dick, 2008; Jha and Dick, 2010).

Both migratory and resident birds have been the focus of multiple studies that have demonstrated that the species richness, abundance, and functional diversity of birds decline with increasing management intensity in Latin American coffee plantations (Greenberg *et al.*, 1997; Matson *et al.*, 1997; Calvo and Blake, 1998; Perfecto *et al.*, 2003; Philpott *et al.*, 2008a; Philpott *et al.*, 2009). Several studies have demonstrated high species richness and abundance of bats in traditional coffee systems (Pineda *et al.*, 2005; García Estrada *et al.*, 2006; Sosa *et al.*, 2008; Williams-Guillén and Perfecto, 2010, 2011). Howler monkeys can use diverse shade coffee plantations as foraging habitat (McCann *et al.*, 2003; Estrada *et al.*, 2006; Williams-Guillén *et al.*, 2006). A variety of medium-sized mammals exploit high-shade coffee plantations in Mexico (Gallina *et al.*, 2009) and show a negative response to intensification (Gallina *et al.*, 2008). However, available evidence suggests that small mammal richness is reduced in coffee plantations and does not clearly relate to management intensity within coffee plantations (Gallina *et al.*, 2008). The effect of management intensity on herpetofauna remains largely uninvestigated. Amphibian species richness declines from cloud forest to shade coffee (Pineda *et al.*, 2005), although forest shade coffee ecotones conserve higher amphibian diversity than higher contrast forest corn edges (Santos-Barrera and Urbina-Cardona, 2011).

The effect of agricultural intensification in coffee plantations on invertebrate groups has also received substantial attention. Coleopteran groups show divergent responses: in some cases, richness and abundance in shade coffee actually exceeds that of primary forest (Pineda *et al.*, 2005). In contrast, scarab beetles show decreases in species richness and evenness in sun versus shade coffee, with shade coffee retaining only a quarter of the species richness observed in forests (Nestel *et al.*, 1993). For a variety of arboreal, ground-nesting, and twig-nesting ants, the richness and abundance is reduced in shade coffee and declines with increasing agricultural intensification (Perfecto and Vandermeer, 2002; Perfecto *et al.*, 2005; Philpott *et al.*, 2008a; Larsen and Philpott, 2009). Nevertheless, ants experience significant declines in richness in coffee versus forest in all but the most rustic coffee systems, and forest-adapted species show particularly strong declines (Philpott *et al.*, 2008a). The diversity of native bees is higher in coffee systems with greater tree species richness and canopy cover (Jha and Vandermeer, 2010). Diurnal Lepidoptera are particularly sensitive, as even the small changes in arboreal diversity and structure in traditional shade coffee plantations are associated with substantial declines in species richness (Perfecto *et al.*, 2003).

Fungal and microbial responses to intensification remain understudied, particularly given the importance of these groups in ecosystem function. Mycelial cord-forming fungi decline substantially between cloud forest and shade coffee (Guevara, 2005). Although saptrotrophic fungi have similar diversity and abundance in forest and different coffee systems, there is substantial species turnover between systems; in contrast, endomycorrhizal richness and abundance decline with increasing management intensity (Heredia Abarca *et al.*, 2008). Published information on soil bacteria is virtually nonexistent, although a study in Indonesia demonstrated increased bacterial diversity in shade versus sun coffee (Evizal *et al.*, 2012).

The role of shade coffee in maintaining biodiversity extends beyond the immediate conservation of species richness within coffee plantations. In many regions of Latin America, shade coffee represents the majority of remaining mid-elevation range forest cover (Perfecto *et al.*, 1996; Perfecto and Armbrecht, 2003); agricultural intensification within these zones could result in the loss of habitat for disturbance-tolerant species in this altitudinal zone. Shade coffee also comprises high-quality matrix that facilitates dispersal between forest fragments; as forests become increasingly fragmented in the tropics, highly permeable matrix like shade coffee will be key to countering biodiversity loss resulting from local extinctions by facilitating dispersal between fragments (Vandermeer and Perfecto, 2007; Perfecto and Vandermeer, 2010). The high-quality agroforestry matrix formed by diverse shade coffee plays a key role in maintaining biodiversity at landscape and regional scales (Perfecto and Vandermeer, 2008, 2010). For example, forest fragments in Colombia maintain significantly greater bat species richness than coffee plantations in a landscape dominated by unshaded coffee; however, in a nearby region dominated by shaded coffee, no significant differences were observed in species richness between forest fragments and coffee (Numa *et al.*, 2005).

Coffee plantations occur in a broader landscape context that can also affect their productivity and provision of ecosystem services. Even landscapes dominated by intensified coffee production often conserve forest fragments, at least in areas too steep to cultivate (Williams-Guillén, personal observation), and farmers may maintain forest fragments specifically for the provision of ecosystem services (Chandler *et al.*, 2013). In northern Costa Rica, members of a local cooperative have adopted an 'Integrated Open Canopy' system, in which smallholder farmers intensify production in a 2–3 ha area and maintain forest on an area of equal size (Arce *et al.*, 2009). At the farm scale, these IOC systems have higher productivity and harbor significantly higher bird diversity than nearby shade coffee systems (Chandler *et al.*, 2013). However, the extent to which this farm-scale diversity translates into increased provision of ecosystem services (e.g., pest control in the case of birds) remains unknown.

Biodiversity and ecosystem function in shade coffee plantations

Less-intensive coffee production systems contribute to a variety of local-, regional-, and global-scale ecosystem services (Jha *et al.*, 2011). As with other agricultural crops, coffee production is dependent on processes, such as pollination, predation, and climate and water regulation. Diverse shade canopies contribute to nitrogen cycling and soil nutrient content (Aranguren *et al.*, 1982; Beer, 1988; Grossman, 2003). High-shade systems are also buffer against variable climates

through increased soil moisture (Lin, 2010) and by reducing variability in microclimate variables (Lin, 2007). Increased shade cover and complexity correlate with reduced disturbance from extreme weather events (Philpott *et al.*, 2008b). These factors directly affect the production and quality of coffee fruits. Although production is widely believed to be higher in lower shade systems, high- and medium-shade systems show few differences in overall yield (Lin, 2009); when controlling coffee plant density, moderate-shade produces the highest yields (Soto-Pinto *et al.*, 2000). Shade cover can increase the quality of coffee produced (Muschler, 2001; Vaast *et al.*, 2005), particularly at lower elevations; this is an important consideration as climate change reduces the optimal areas for coffee cultivation (Jha *et al.*, 2011). Shade coffee can also reduce labor and herbicide inputs, as shade cover decreases the growth of competing herbaceous vegetation (Beer *et al.*, 1997; Muschler, 2001).

A variety of regulating services mediated by animal biodiversity also increase coffee production. Although coffee can be wind pollinated, its fruit set and quality is increased in the presence of nonnative (Roubik, 2002) and native (Klein *et al.*, 2003; Ricketts, 2004) bees. As a result of proximity to forest fragments that harbored increased diversity of native bees, the pollination services to a single coffee plantation in Costa Rica were valued at approximately US$60 000 per year (Ricketts *et al.*, 2004). Pollination services provided by native bees are associated with increased bee diversity (Klein *et al.*, 2003; Ricketts, 2004). The richness and diversity of native bees is increased in diverse shade coffee systems (Jha and Vandermeer, 2010); pollination services are, therefore, presumably enhanced in traditionally managed shade coffee, although the interaction between coffee management intensity and the presence of forest fragments in the landscape remains unexplored.

Although coffee is a well-defended plant, it is vulnerable to attack by a variety of insect pests that are, in turn, limited by the diverse assemblages of predators found in shade coffee. Exclosure experiments have demonstrated that birds, bats, and lizards limit the abundance of herbivores in coffee plantations (Borkhataria *et al.*, 2006; Williams-Guillén *et al.*, 2008; Johnson *et al.*, 2009). The abundance of bat predators increases with decreasing management intensity (Williams-Guillén and Perfecto, 2010, 2011), and the effectiveness of bird-mediated predation decreases in low-shade coffee (Perfecto *et al.*, 2004), suggesting that biocontrol by these generalist vertebrate predators is negatively impacted by intensification.

The coffee berry borer (*Hypothenemus hampei*, Coleoptera: Curcolionidae) is the most devastating insect pest of coffee (Damon, 2000). Native to Africa, the life cycle of this pest makes it difficult to control, as it spends the majority of its lifespan within coffee beans (Vega *et al.*, 2009). However, a variety of generalist predators impact the populations of this pest. In Jamaica, exclosures designed to keep birds from foraging in shade coffee resulted in doubling the proportion of coffee berry borer infestation (Kellermann *et al.*, 2008; Johnson *et al.*, 2009). The pest control services provided by vertebrate predators in coffee plantations have been valued at US$75–310 ha^{-1} $year^{-1}$ in terms of pest damage prevented (Karp *et al.*, 2013; Kellermann *et al.*, 2008); several bird species identified as important for berry borer and insect pest control, such as the Tennessee warbler (Philpott *et al.*, 2009) and rufous-capped warbler (Karp *et al.*, 2013), rely on trees in coffee farms for foraging or are more abundant in farms with more tree cover and most likely would provide limited benefits in intensive sun coffee systems due to the lack of shade cover.

The ecosystem services produced by shade (vs. sun) coffee production extend far beyond the local farm scale. Coffee cultivation contributes to watershed conservation, soil protection, and buffering negative effects of extreme weather events (Jha *et al.*, 2011). Shaded systems have more favorable and stable microclimates and suffer reduced water loss (Lin, 2007). Higher shade systems also suffered reduced landslides in the wake of a major hurricane (Philpott *et al.*, 2008b). Shade coffee also forms high-quality matrix that facilitates the dispersal of native wildlife across longer distances and between protected areas (Jha *et al.*, 2011). Increased permeability of matrices of shade versus sun coffee increases movements of key pollinators, seed dispersers, and predators, enhancing the ecological stability of protected areas in mountainous regions and at the same time providing increased opportunity for provision of ecosystem services within farms.

At a global level, one of the most critical ecosystem services that shaded coffee systems can provide is the sequestration of carbon, thus mitigating climate change. Tropical agroforestry systems may sequester more than 200 MT of carbon per ha (Albrecht and Kandji, 2003) in plant biomass and soil. In Mexico, carbon stocks were 22 times higher in coffee plantations than in maize cultivation (Soto-Pinto *et al.*, 2010), whereas in Togo, inclusion of even a simple shade layer over coffee increased carbon stocks by 3.5 times to 81 MT per ha (Dossa *et al.*, 2008). However, practices, such as fertilization and use of nitrogen-fixing shade trees could increase the emissions of other greenhouse gasses from coffee plantations, indicating that careful consideration of inputs and shade trees must be made in order to evaluate the overall impact of shade coffee on climate change mitigation (Jha *et al.*, 2011). Nevertheless, in a warming world, shade cover will most likely play a critical role in maintaining coffee cultivation as current growing regions become suboptimal due to increasing temperatures, changes in precipitation patterns, and more frequent hurricanes, all of which can be buffered through a shade canopy (Jha *et al.*, 2011).

Despite the system's reputation for sustainability, coffee cultivation can generate substantial ecological disservices. Deforestation, erosion, nutrient loss, and instability of microclimate can all result from the conversion of forest or high-shade systems to low-shade or sun coffee. In Latin America, coffee cherries are commonly processed via a 'full wash' method to remove coffee pulp and mucilage from the fruit before drying; although this produces a higher quality bean, the process produces large amounts of effluents that can contaminate local water supplies (von Enden *et al.*, 2002). Use of agrochemicals in coffee plantations presents immediate threats to workers applying chemicals (often without the use of adequate protective gear) as well as to local communities living with runoff. The most commonly used insecticides for coffee berry borer control, endosulfan and chlorpyrifos, are highly toxic (Jaramillo *et al.*, 2006). Plantings in extremely steep areas may lead to erosion, and replacement of forest with

coffee leads to biodiversity loss and potentially reduced watershed protection and climate mitigation.

Market Incentives to Conserve Ecosystem Services in Coffee

Existing Mechanisms

Given its economic and social importance, not surprisingly a number of mechanisms falling under the broad umbrella of Payments for Ecosystem Services exist for coffee. These schemes include certification of preferred production systems, direct payments to producers from governments or individuals, and participation of farmers in environmental markets.

Certification schemes

Certification programs are the most widespread and well-recognized mechanisms for compensating farmers for conservation of biodiversity and provision of ecosystem services. Under such programs, farmers adopt specific production criteria established by third parties, contract auditors to inspect and verify adherence, and receive in return the right to sell and market their product as certified. Although such systems may involve substantial costs for producers, the expected benefit is the ability to sell their crops at a price premium to consumers willing to spend more to support such systems. Certified coffee (e.g., organic, fair trade, etc.) accounts for approximately 10% of global production (Jha *et al.*, 2011). These certification and labeling initiatives are voluntary and private, without governmental mandate (Raynolds *et al.*, 2007).

Certified organic agricultural production is an example of a certification scheme familiar to most readers, in which production without the use of agrochemicals results in a more valuable crop. Organic certification is applied to a variety of crops globally; in case of coffee, organic certification generally involves the use of composting organic material, improvement of soil nutrient content, and prevention of erosion and soil runoff (Giovannucci and Koekoek, 2003); organic certification makes no demands with respect to tree cover or maintenance of forested areas. Thus, although organic production may improve provisioning of ecosystem services related to soil conservation, intensive organic systems may provide reduced regulating and provisioning services than traditional – but not organic – shade coffee plantations. For example, when canopy structure is held constant, organic production had no effect on the diversity or abundance of trees or birds in Nicaraguan shade coffee (Martínez-Sánchez, 2008).

A second widespread certification program applied to coffee is Fair Trade, which promotes price premiums for smallholder farmers and cooperatives exporting from the developing to the developed world. Although Fair Trade criteria focus on social and economic aspects of production, they also include limitations on the use of toxic agrochemicals, buffer zones around water resources, and ban the use of genetically modified crops (Jha *et al.*, 2011; Raynolds *et al.*, 2007). As is the case with organic certification, there are few provisions to ensure the maintenance of shade cover that enhances the provision of ecosystem services, although Fair Trade certification may have positive impacts on the provision of water and reduce agrochemical contamination as a result of measures meant to insure worker safety. Nevertheless, the focus on small producers may indirectly promote shade coffee, because smallholder farmers tend to use less labor-intensive shaded systems (Perfecto *et al.*, 2005). More recently, UTZ certification has become available for coffee and other tropical export crops with broadly similar criteria to those of Fair Trade (Giovannucci and Koekoek, 2003) focused on compliance with local labor and environmental laws.

In the 1990s, coffee certification programs that emerged focused on the certification of 'eco-friendly' coffee, more explicitly taking into account production methods and their effects on biodiversity and ecosystem service provision (Raynolds *et al.*, 2007). The Smithsonian Migratory Bird Center's Bird-Friendly® program is among the most stringent of these, requiring organic production, the use of at least 10 shade tree species with minimum heights of 12 m, three canopy layers, maintenance of lianas, and a minimum shade cover of 40% (Smithsonian Migratory Bird Center, 1998). Participants are small producers, and this certification comprises a small proportion of exports in the certified coffee market (Raynolds *et al.*, 2007). Although the provision of ecosystem services in Bird-Friendly® versus noncertified shade coffee has not been quantitatively evaluated, such management would presumably provide the widest variety of services. Rainforest Alliance's 'Sustainable Agricultural Network' standards include a variety of social and ecological criteria; the latter are less stringent than those of the 'Bird Friendly' program but include provisions for maintenance of diverse shade trees on farms with a minimum shade cover of 40%, protection of natural ecosystems and riparian buffers, wastewater treatment, use of integrated pest management techniques, and reduced agrochemical use (Hughell and Newsom, 2013). A recent contrast of certified and noncertified plantations in Columbia suggests that such certification has a positive impact on the provision of ecosystem services: certified farms had higher water quality and healthier streams, increased arthropod species richness, increased use of 'best management' practices, and increased revenues (Hughell and Newsom, 2013).

Direct payments

With direct payments, rather than receiving a price premium for coffee produced using methods that maintain ecosystem services, coffee producers receive direct payments from beneficiaries, usually through an institutional intermediary. Thus, incentives for maintaining ecosystem services are not tied to coffee commodity prices, which can undergo large and rapid price fluctuations (Jha *et al.*, 2011).

Although Payment for Environmental Services (PES) schemes have received widespread attention and are considered a promising approach, relatively few real-world examples exist from the tropics (Wunder, 2006). Despite widespread recognition of the potential to incorporate shade coffee production into PES for carbon sequestration and watershed protection (Rosa *et al.*, 2004; Montagnini and Nair, 2004), only a few initiatives specifically target small-scale shade coffee production (Méndez *et al.*, 2010a). Moreover, coffee plantation owners who maintain forest fragments on their properties could conceivably receive payments under

Costa Rica's PES program that rewards landowners for maintaining forested areas.

An example of a localized PES scheme involving coffee production comes from Honduras, where the community of Jesús de Otoro relies on water from the Cumes River (Kosoy *et al.*, 2007). This source of drinking water was becoming contaminated due to coffee cultivation upstream. A local grass roots water council of elected representatives (JAPOE, Council for Administration of Water and Sewage Disposal) created a PES scheme with the assistance of the nonprofit organization PASOLAC (Program for Sustainable Agriculture in the Hillsides of Central America), in which downstream users pay a fee of approximately US$0.06 per household per month to compensate upstream farmers for adoption of improved waste management practices and protection of forests (Kosoy *et al.*, 2007). Although downstream users report improvements in water quality, the low payments to upstream producers have hampered adoption, covering only 70 of the 200 ha identified as high priority for participation (Porras and Neves, 2010).

Tax incentives and agrotourism may also be seen as forms of direct payments in exchange for ecosystem services. The latter in particular is well developed in coffee plantations. In the Soconusco region of Chiapas, Mexico, several of the large coffee plantations have established tourist hotels and restaurants catering to weekend visitors and international tourists interested in bird watching and hiking (Anonymous, 2009).

Environmental markets

In the case of environmental markets, the ecosystem service itself is marketed and sold as a commodity to a beneficiary (usually an institution rather than individual) in the context of a dedicated market, usually subject to oversight by a regulatory body (Stuart *et al.*, 2010). Carbon credits and offsets are the most prominent example of such markets and the one with great potential but limited implementation in agroforestry systems, such as shade coffee.

One of the few success stories involving the sale of carbon from coffee plantations comes from the Scolel Te' program in central Chiapas, Mexico. The program was designed for researchers at the University of Edinburgh with the express goal of creating a market for the ecosystem services generated by agroforestry systems (Tipper, 2002). In this program, participating farmers develop plans for sustainable agroforestry and reforestation; based on estimates of carbon sequestered, they receive ex-ante carbon offset payments (US$12 MT^{-1} C in 2002; Tipper, 2002). The program is managed by the nonprofit AMBIO, which evaluates farmer management plans and estimates the amount of carbon to be sequestered as a result of the planned management and reforestation interventions. The program has grown rapidly: as of 2010, nearly 2500 registered producers managing more than 9500 ha of land had enrolled, and approximately US$109 500 worth of payments were made in 2010 (Quechulpa Montalvo and Esquivel Bazán, 2011). The program has additional social and educational benefits for producers through training and educational opportunities. This community-based carbon credit framework has since been consolidated as the Plan Vivo Standard, with registered projects across the globe subject to long-term third-party monitoring and selling Plan Vivo Certificates representing 1 MT of reduced or avoided carbon emissions (Anonymous, 2008). The up-front costs of entry into certification plans and green markets are often a deterrent to the participation of smallholder farmers; thus, the Plan Vivo standard represents one of the few success mechanisms by which the majority of producers in developing nations have access to these emerging markets. Nevertheless, the short fallings of these mechanisms are as numerous as their successes.

Failure and Weakness of Current Market Mechanisms to Conserve Ecosystem Services

Although market-based mechanisms for incentivizing the provision of ecosystem services have shown some early successes (Hughell and Newsom, 2013; Quechulpa Montalvo and Esquivel Bazán, 2011), the limited number of programs as well as the failure of well-established certification programs speaks of the weakness of currently existing schemes. Aside from the single study commissioned by Rainforest Alliance (Hughell and Newsom, 2013), no other research that has explicitly contrasted the provision of ecosystem services (or reasonable proxies, such as bee diversity as an indicator of pollinator services) in certified versus noncertified coffee farms is known. Thus, despite the sound and fury, the certification that serves to protect biodiversity or ecosystem services with coffee farms or other agricultural systems remains largely an article of faith. There is a clear research need for studies to investigate the ecological (rather than socioeconomic) effects of certification schemes.

As mentioned previously, certification schemes, such as Fair Trade and organic, may do little to directly safeguard a variety of ecosystem services, which is a weakness of the major certification programs if they are not explicitly linked to parallel programs that emphasize conservation of ecosystem function (Philpott and Dietsch, 2003). The volatility of current agricultural markets contributes to undermining the efficacy of certifications in maintaining biodiversity and ecosystem services. In the late 1990s, coffee prices underwent a precipitous decline in the wake of market liberalization, the dissolution of agreements setting international coffee prices, and a glut of production from Southeast Asia (Bacon, 2005); as a result, the labor costs of harvesting coffee exceeded the prices the cherries could fetch, with the result that coffee crops were left to rot on the plants (Williams-Guillén, personal observation). At one Costa Rican shade coffee farm, pollination services had been valued at >US$60 000 per year (Ricketts *et al.*, 2004); nevertheless, in the wake of the 'coffee crisis,' the plantation was transformed from coffee to intensive pineapple production (McCauley, 2006). Ecosystem services tied to the valuation of a crop are as vulnerable to market fluctuations as the crop itself.

It has been suggested that coffee certification itself could lead to more deforestation (and hence reduced provision of ecosystem services at regional scales) because an increase in coffee prices could incentivize expansion of coffee production into forested areas (Rappole *et al.*, 2003; Tejeda-Cruz *et al.*, 2010). However, despite price premiums received by smallholder producers of organic and Fair Trade certified coffee, overall impacts on household livelihoods are insignificant for most metrics as a result of limited per household production

and inability to sell entire harvests at certified prices (Méndez *et al.*, 2010b). Many types of certification are outside of the reach of small-scale producers due to up-front costs associated with enrollment (Gobbi, 2000). Although certified coffee is a growing sector, at present it comprises less than 2% of global coffee production (Méndez *et al.*, 2010b), and production for some markets currently outpaces demand (Giovannucci and Koekoek, 2003). Thus, although certification produces financial benefits for large-scale producers and highly organized cooperatives, as a measure for incentivizing the maintenance of ecosystem services in coffee plantations (and other agricultural landscapes), it is inadequate to protect ecosystem services as currently practiced – price premiums in general fail to offset increased production costs, and relatively few consumers in developed nations are interested in voluntarily paying for the 'real' cost of their coffee that integrates the externalities of human and ecosystem health.

The dearth of examples of the use of direct payments for ecosystem services speaks to some of the main challenges in the use of this system in developing nations. Such schemes depend on strong, transparent government agencies or institutions capable of regulating payment mechanisms; however, weak governance and corruption are the norm in the global south. Sustainable funding for direct PES is a second challenge, even for well-established programs: despite taxes to beneficiaries, Costa Rica's PES program relies partially on loans and grants from development agencies (Pagiola, 2008). The example of direct PES to coffee producers in Honduras highlights the need for payments to realistically offset the opportunity costs (i.e., the revenue lost by making a different choice, in this case, choosing not to invest in wastewater treatment). Low payments to producers have hampered adoption, resulting in low adoption rates and limited protection of the watershed. This example speaks of the broader issue of valuation within the design of PES schemes. Without accurate estimates of the monetary benefits of provisioning of ecosystem services, it is difficult to assess appropriate payments to providers (Kroeger and Casey, 2007). Given the impossibility of carrying out quantitative studies to estimate ecosystem service value in every local context, the development of spatially explicit modeling tools to estimate values and trade-offs between services is a key advance that will facilitate small-scale PES implementation (Kroeger and Casey, 2007; Tallis and Polasky, 2009). Initiatives, such as InVEST, promise to provide such tools (Nelson *et al.*, 2009), although their utility in real world situations remains largely untested.

Kroeger and Casey (2007) outline additional weaknesses in market-based approaches, which are apparent even in the relatively successful example provided by Scolel Te' example. Carbon sequestration provides an example of a nonexcludable service: beneficiaries will receive the service of carbon sequestration whether or not they pay to support reforestation and agroforestry. Thus, voluntary markets and programs will often fail to produce the funding needed to provide adequate payment to farmers, because it easy for beneficiaries to avoid payment and 'cheat the system.' For example, market fluctuations, the effects of economic recession, and other factors can result in low sales of carbon credits and hence reduced payments to Scolel Te' participants (Quechulpa Montalvo and Esquivel Bazán, 2011). Such market fluctuations effectively cause an increase in opportunity costs; if payments do not increase in tandem to offset these increases, producers may leave programs to pursue more intensive or expanded agriculture. The limited standards and monitoring protocols, coupled with a lack of global leadership to institute cap-and-trade programs, form a major limitation of environmental markets. Because large-scale environmental markets are unlikely to develop in the absence of regulations compelling participation on the parts of beneficiaries, such market-based mechanisms will remain limited in the current climate of market liberalization and deregulation.

Strategies and Opportunities for Improving Conservation of Ecosystem Services through Market Incentives

Lessons from Successful Programs

The Scolel Te' program provides one hopeful example for a successful PES approach in the developing Latin America. Because the program was designed to seek payments for traditional agroforestry practices already familiar to many producers (as opposed to seeking to radically change production techniques), adoption rates were high (Tipper, 2002). Nevertheless, other PES programs focused on modifying production systems have also met with success. For example, a program in Nicaragua used PES to incentivize the adoption of silvopastoral systems by ranchers, funded by the global environment facility; the program was well received by participants and produced improvements in indicators of ecosystem health (Pagiola *et al.*, 2007). Most participants maintained the improved systems after the end of the official project period and guaranteed payments, and the municipal government introduced tax incentives for producers (Svadlenak-Gomez, 2009). However, sustained funding for payments and weak local governance remain challenges for the long-term survival of the program (Svadlenak-Gomez, 2009).

PES schemes related to food systems can also serve to fill gaps in service and enforcement in the case of weak institutions with limited resources. A second example of a successful PES program comes from southwestern Nicaragua, where the Non-governmental organization (NGO) Paso Pacífico partnered with a government-administered wildlife reserve and local fishing communities to develop a performance-based incentives program to curtail the poaching of sea turtle eggs for local and national consumption (Smith and Otterstrom, 2009). Through this program, would-be turtle egg poachers are offered a modest payment in exchange for committing to protect a turtle nest by becoming 'nest protectors.' On successfully protecting a turtle nest, 'nest protectors' are then given a payment for each nest successfully protected. The price paid is above the market price for eggs. These performance-based incentives are a form of direct payments for conservation with the buyer being the environmental NGO. During the course of the program, poaching on the participating beaches dropped from nearly 100% to 15%. A key component of the program's success was participation of local community representatives in developing payment mechanisms, timely payment of incentives that were on a par with

opportunity costs, and transparency on the part of Paso Pacífico in the administration of the program. As with many PES programs, a key limitation was sustained funding: despite the program's success, it continues in a limited capacity on only one beach due to limited funding streams from granting agencies. Future options for developing sustainable funding streams include linking to incipient biodiversity markets, in which fisheries companies could, for example, purchase 'turtle credits' to fund the protection of nesting beaches to offset the accidental mortality of juvenile and adult sea turtles incurred during fishing.

Opportunities and Future Directions for Payments for Environmental Services in the Agricultural Landscapes of Latin America

Although the past years have seen some development of market-based mechanisms for conservation of ecosystem services in agricultural landscapes, such schemes remain a promise rather than a reality for the vast majority of producers in developing regions even when considering only the relatively valuable crop of coffee. A variety of factors, from volatile markets to weak governance, remain a barrier in using such incentives to promote conservation among agriculturalists of the global south. A recurring theme in the success of PES programs in Latin America has been the involvement of local nongovernmental institutions with close ties to the communities targeted for payments; these communities often present well-organized, semiautonomous governance, echoing arguments that local social movements must play a key role in successful conservation in developing nations (Perfecto *et al.*, 2009). Partnership with academic institutions in the development of program structures has also played a key role in successful examples, particularly in larger scale programs. Finally, programs designed with systematic input from local communities have been a clear component in success, particularly when the involvement of local governmental bodies reinforces norms and incentives. 'Top–down' approaches have produced some success, particularly when based on modifications of already-established policies (Pagiola, 2008). However, when such approaches overlook meaningful community participation, they often fail, whereas 'bottom–up' approaches based on interventions suggested by target communities tend to fail due to lack of resources; this situation highlights the need for 'hybrid' approaches that unite the resources of larger institutions with the insight and momentum of local, grassroots organizations (Méndez *et al.*, 2010a). In Latin America's developing nations, NGO intermediaries with close connections to local producers and relationships with institutional representatives are a key link in the design and effective implementation of PES schemes.

Given the limited availability of environmental markets and the technical and economic barriers to certification schemes, direct payments for conservation may be the most feasible approach in Latin America, at least in the short term. It is believed that small NGOs with conservation goals, meaningful relationships with small-scale producers, and the knowledge necessary to negotiate agreements with private industry and government stakeholders are a key nexus in uniting a variety of stakeholders to generate demand for the conservation of biodiversity and ecosystem services and biodiversity in the working landscapes that will most likely characterize much of the tropics in the twenty-first century.

Conclusion

Ecosystem services are fundamental to the success of agriculture, and agricultural production can produce a number of ecosystem services and disservices at local, regional, and global scales; nevertheless, examples of market-based mechanisms to conserve these services are limited (Kremen and Miles, 2012; Kroeger and Casey, 2007; Power, 2010). Although several existing mechanisms have the potential to compensate farmers in the developing world for conserving and maintaining ecosystem services, at present these programs are at incipient stage and have demonstrated both promise and pitfalls.

The most successful programs involve participation of governmental, nongovernmental, and academic institutions; integration of top–down and bottom–up solutions and mechanisms; and buffering smallholder producers against fluctuations in market prices (of both agricultural and ecological commodities). Demand for agricultural products in low- and middle-income countries is expected to double by 2050 (Food and Agriculture Organization of the United Nations, 2011); without concerted attempts to internalize the market externalities of ecosystem services, this increased demand will undoubtedly result in massive environmental degradation and the ultimate failure to provide adequate resources for the majority of the world's human population. Market-based incentives can play a key role in safeguarding ecosystem services in agricultural areas, but their implementation is limited by lack of adequate policy and regulatory mechanisms, sufficiently large incentives to offset opportunity costs, and the failure of stakeholders to unite top–down and bottom–up approaches that integrate the regulatory capacity of governments with participatory action from producers to design appropriate local models for compensation.

Within the developing world, weak governance and inequitable distribution of resources are fundamental barriers to the optimal function of market-based mechanisms. In these cases, nonprofit organization, academic institutions, and grassroots community organization play vital and complimentary roles in developing appropriate and effective methods to protect interests and sustainability of local and global populations. Much of the current degradation in ecosystem services has resulted from the market failures inherent to neoliberal priorities of deregulation and privatization; expecting market-based interventions to resolve problems caused by markets themselves is more likely a losing proposition. Ultimately, market-based approaches to conservation are only one component of a larger toolkit that incorporates concepts of the intrinsic value of nature and also a focus on economic productivity, social equity, and sustainable livelihoods (Perfecto *et al.*, 2009).

Markets and Prices

JM Welch, CE Shafer, and DA Bessler, Texas A&M University, College Station, TX, USA

© 2014 Elsevier Inc. All rights reserved.

Glossary

Demand Quantity of a particular commodity which a consumer is willing to purchase as its price varies, assuming all other factors are held constant.

Market Place (perhaps a physical place but not necessarily) where buyers (demanders) and sellers (suppliers) of a commodity come together to negotiate an exchange at a price.

Money The numerable commodity or asset in an economy that serves as the most common means of exchange for goods and services.

Price The basic signal of exchange in economic systems. Price represents the rate at which one commodity (good) is exchanged for another commodity.

Supply Quantity of a particular commodity which is offered for sale per time period as price varies, assuming all other factors are held constant.

Price Functions

Price serves two major functions: first, to ration scarce commodities (who gets what) and second, to motivate (direct) future production of commodities (what products will be produced). The manner in which price carries out these functions differs according to the institutional rules (rules of the game) placed on the market. These rules range from very little regulation (asset prices in auction markets, e.g., futures markets for crops, livestock, and financial instruments in the US) to extreme forms of regulation where price is fixed by governmental authority. Two forms are described – free markets with little or no regulation except legal requirements of enforcement of contracts and type of communication among buyers and sellers (double oral auction vs. posted prices) and fixed price markets. The efficiency with which price is able to carry out the above mentioned functions is determined by the institutional rules placed on the market.

Some criteria useful for measuring the efficiency and performance of a pricing system include (Forker, 1975):

1. Allocation efficiency including short-run market clearance, inventory adjustments, production adjustments, and marketing efficiency.
2. Welfare considerations regarding price level and stability, price dispersion, and sharing of gains or losses within the marketing channel.
3. Competitive considerations on market access, bargaining power, structure, and information flow.
4. Cost considerations including waiting time and transportation and system costs.
5. The level of buyers' and sellers' satisfaction with the operation and results of the system.

Equilibrium Price

In free markets, price adjusts according to changes in supply and demand; the market price is that which just clears the market – the amount of the commodity suppliers want to supply (give up title to) equals the amount of the commodity demanders want to purchase (Mankiw, 2012). Generally, quantity supplied is a positive function of price, so that suppliers (those who hold title to the commodity) offer more for exchange (are willing to give up more of the commodity, possibly because they produce more of it) when price increases, whereas quantity demanded is a negative function of price, as demanders (people who do not have title to the commodity but may perhaps want to acquire title to it) offer to buy less when price increases. If the quantity that suppliers offer at a specific price is greater than the quantity that demanders wish to purchase at that price, price will fall, inducing demanders to take more. The reverse will occur if the quantity that suppliers wish to supply at a given price is less than the quantity that demanders wish to acquire at a specified price. Price arrived at in free markets by this interaction of supply and demand is called an equilibrium price, as there will be a tendency for price to return to this level if there is some small perturbation away from it.

Price arrived at through the interaction of demand and supply reflects the marginal valuation of the group (society) for the particular commodity. This explains the seemingly odd fact that a commodity as useful as water (say an acre foot of water) has a price much lower than an apparently less useful commodity, say a one carat diamond of high quality. The latter is of limited supply, whereas the former is of much greater supply. However, if constraints are placed on the availability of water, it would be seen, rather quickly, that its price would be equal to or much greater than that of a diamond. The marginal utility of a unit of water is much less than that of a diamond, but the total utility of water is much greater.

In free markets, those individuals who are willing to pay the market price will be able to acquire the commodity, whereas those who are neither willing nor able to pay the price do without. The entire amount brought to the market (amount suppliers are willing to put on the market) is rationed (allocated) among users by price. If the price arrived at in free market equilibrium is high (relative to the cost of producing the product), suppliers in future periods will have an incentive to bring forth additional supplies of the commodity. If the price is below the cost of production, suppliers will bring forth smaller quantities in future periods. Thus, price serves its

 doi:10.1016/B978-0-444-52512-3.00113-3

second function: directs (motivates) what and how much is to be produced.

Planning Prices

In regulated markets, the extent to which price can accomplish its two functions is blurred. In extreme cases where price is held fixed by government authority, both the rationing and direction functions are stifled. For example, in centrally planned or command economies, where price is not allowed to adjust according to market demand and supply, rationing is accomplished on a first come, first served basis. Once the entire supply of the product is sold at the fixed price, waiting lines form, until additional product is brought to the market. Here price does not perform the rationing function. Rather, time spent in line does the rationing. In such cases, it is common for parallel or black (illegal) markets to form, which mimic the behavior of a free market.

The direction of production is also impaired in fixed price markets. If the price is set above the free-market equilibrium price, suppliers will have an incentive to produce more of that product (more than demanders wish to purchase). Such products will sit in inventory (wait to be sold). If price is set below the equilibrium price, producers will have no incentive to produce additional units of that commodity, even though demanders would be willing to pay more for additional quantities of that commodity. Thus, surpluses and shortages occur too high and too low, respectively, at fixed prices.

In centrally planned economies, provisions for changing price and production have been devised which rival market prices, at least, in theory (related works of Lange, 1936 and Lerner, 1934 develop this model and a critical comment is offered in Friedman, 1947). Prices in centrally planned economies were modeled to provide much of the same information as prices from free markets offer. Essentially, this model works by accounting prices and information interchanges between managers and the central planning authority. The central planner sends information to the managers in the forms of a set of price signals; the manager returns information to the central planners in terms of his/her output, if this planned output was greater than needed, a new set of accounting prices would be communicated to the managers. This process continues until a particular set of production levels are realized. Lerner (1944) argued that such a system could replicate the market pricing system. Although the Lerner model was never actually tested, the late 1980s to early 1990s collapse of the centrally planned economies of Eastern Europe suggests that the system may have suffered in application. It is difficult for central planners to gather even a fraction of the information relevant to production and consumption decision making that is conveyed by price in a free-market economy (Landsburg, 2011).

The price emanating from these planning models is a 'shadow price' which gives the marginal valuation of the resource (production constraint) in the model. As these prices are not necessarily seen in the market (but are the output from the mathematical model), they are labeled 'shadow prices.' Those constraints for which all of the resource is utilized will have nonzero shadow prices.

Price in Agricultural Markets

Agricultural markets are interesting because their demand functions (described generically above) are believed to have particularly inelastic form. When a demand function is inelastic, the percentage changes in quantity demanded due to a percentage change in price is small compared with a more elastic demand schedule (see **Figure 1**). The reader may grasp the relevance of this point by understanding that certain commodities have few substitutes. Food (as a composite commodity) is one such commodity. Consumers are not likely to change their previous level of food consumption due to a change in the price food. Food is quite habit forming and perishable.

Weather uncertainty leads to variable production which interacts with the inelastic demand, resulting in highly variable agricultural commodity prices. In markets characterized by inelastic demand functions, relatively small change in supply can have a large price impact (see **Figure 2**). Accordingly, market institutions which deal with high price variability, directly or indirectly, have found extensive use in agriculture.

Figure 1 Impact on quantity demanded with a decrease in price, comparing inelastic and elastic demand functions.

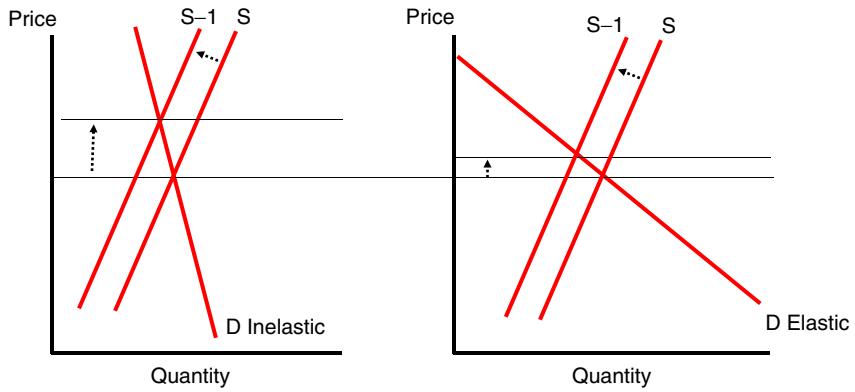

Figure 2 Impact on price with a decrease in supply (S), comparing inelastic and elastic demand functions.

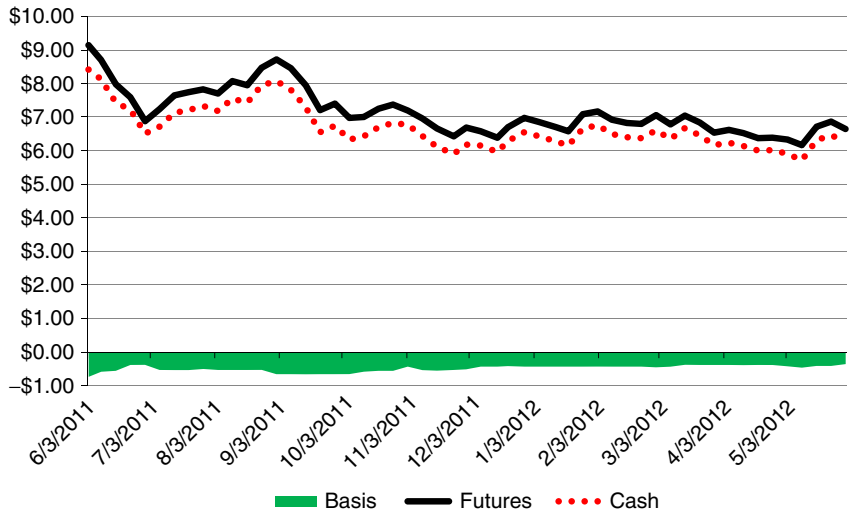

Figure 3 Wheat prices: Kansas City futures, Texas cash (spot, USDA-Ag Market News Service, www.ams.usda.gov/mnreports/AM_GR100.txt), and Texas basis.

The major market risk-bearing institutions are agricultural commodity futures markets, insurance contracts, and federal government programs.

Futures Prices

Organized futures markets which allow both producers and consumers to reduce market price uncertainty through hedging have existed in the US for well more than 100 years. Holbrook Working (1953) aptly defined hedging as using the futures market as a temporary substitute for the cash market. A futures market is a centralized market where futures contracts are traded in organized exchanges, either by open outcry, electronically, or both. A futures contract is a legally binding standardized agreement (conditions set by the exchange) to buy or sell a commodity specifying quantity, quality, and date and place of delivery. The only nonestablished variable is the price. In this way, the futures price is a statement of a commodity's value at a specific point in time at a particular location.

Forward pricing using futures contracts is based on the premise that, over time, the local cash price and futures prices move together. Therefore, adjusting for local conditions, pricing in the futures market is a close approximation to pricing in the cash market. The amount that the local cash (spot) price of a commodity is above or below the futures price for a particular month is called the basis (basis = local cash price minus futures). Although most of the differential between the local cash price and the futures price can be explained by storage and transportation costs between a user's or producer's local cash market and the exchange-specified futures market delivery point, local supply and demand conditions can also affect the amount of the basis.

Basis risk, the variability between local and futures prices, is generally much less than the price risk associated with the commodity. Figure 3 shows the relationship between the price of hard red winter wheat grown in Texas and the Kansas City Board of Trade exchange futures price (with delivery points of Kansas City, Missouri, Hutchinson, Kansas at a 9 cent discount, Salina/Abilene, Kansas at a 12 cent discount, and Wichita, Kansas at a 6 cent discount). In the 2011–12

marketing year, the average amount by which the Texas cash price of wheat was below the Kansas City futures price was 48 cents per bushel, in a 38 cent range from US$0.35 to US$0.73. Over this same period of time, the highest futures price was US $9.14 per bushel and the lowest was US$6.18 per bushel, a price range of US$2.96.

Very few buyers or sellers of futures contracts actually make or take delivery of physical commodities. Instead, they offset their positions in the futures market (buying back contracts if they sold and selling back contracts if they bought). Because futures and cash markets move together, any loss in the cash market is offset by gains in the futures market and vice versa.

Take the case of a Texas wheat farmer who plants in October and will harvest wheat the following June. He/she observes that the July futures contract for Kansas City wheat (the nearest, but not before, harvest-time contract offered) is US$8.00 per bushel. He/she is concerned that prices will fall between now and harvest and decides to hedge. He/she calls his/her commodity broker and sells the equivalent number of futures contracts to cover his/her expected production. His/her local basis at harvest is normally US$0.60/bushel. This action establishes an expected hedged cash price of US$7.40 per bushel (US$8.00 futures plus US$0.60 basis) (Ignoring brokerage commissions). At harvest, the price of the July Kansas City wheat contract is US$7.00 per bushel; the local basis is US$0.60. He/she sells his/her wheat in the local cash market for US$6.40 per bushel (US$7.00 futures plus US $0.60 basis) and buys back his/her futures contracts for a profit of US$1.00 per bushel (US$8.00–7.00=US$1.00). Adding the dollar profit from his/her futures transactions to his/her cash wheat price returns US$7.40 per bushel, the price he/she sought to lock in with his/her hedge. Had the futures price increased, say to US$9.00 per bushel, and the basis held steady at US$0.60, he/she would have sold wheat at harvest in the cash market for US$8.40 per bushel and subtracted a net loss in the futures market of US$1.00 per bushel from his/her wheat returns, again leaving him/her with a hedge price of US $7.40 per bushel. The uncertainty in the cash market price has been reduced by his/her equal but opposite participation in the futures market. The farmer remains subject to yield uncertainty which may not be particularly easy to forecast but can be partially covered by crop insurance.

The farmer who protected against a drop in his/her local cash market price by creating a short hedge with futures, also 'protected' against the benefit of a price increase during the course of the hedge. In 1984, a type of 'price insurance' in the form of commodity options on futures contracts became available for a premium. An option is the right, but not the obligation, to buy or sell something at a predetermined price (the strike price) at anytime within a specified time period. A put option gives the buyer the right to sell the underlying commodity; a call option gives the buyer the right to buy the underlying commodity. In the present case, the underlying commodity is a futures contract.

If the futures price falls below the option strike price before the option expires, the buyer of the put option could exercise his/her right to sell futures at the predetermined strike price. If price rises, the producer would not use (exercise) the option but simply sell the crop at the higher cash price level at harvest. Options in agricultural commodities typically expire at the end of the month before futures contract expiration, for example, the latter part of June for a July futures contract. At option expiration, the only value the option contract will have is the positive difference between the strike price and the underlying futures price. If the futures price is equal to or greater than the strike price, the option will expire worthless.

Instead of hedging and locking in a net expected hedged price of US$7.40 per bushel for his/her wheat, the farmer could have bought a put option. If a put with an US$8.00 strike price were selling for US$0.50 per bushel, he/she would have purchased the right, but not have the obligation, to sell (take a short futures position) July Kansas City wheat for US $8.00 per bushel anytime between the purchase date and option expiration. For that right, he/she would pay the option seller US$0.50 per bushel. Assuming he/she holds on to that option until harvest (and option expiration) in June, and the price of wheat falls to US$7.00 per bushel and the basis is US$0.60, he/she would sell his/her wheat in the cash market for US$6.40. His/her option position would have profit of US$1.00 (US$8.00 strike price minus US$7.00 futures) less the premium paid (US$0.50). His/her net wheat returns would be US$6.90 per bushel (US$6.40+1.00−0.50). This compares to wheat returns of US$7.40 if he/she hedged and US$6.40 by doing nothing (see **Figure 4**). If the price of wheat at harvest was US$9.00 per bushel, his/her option would expire with no value because the underlying futures price is greater than the strike price. In this case his/her returns from selling wheat would be US$8.40–0.50 premium paid or US$7.90 per bushel (US$8.40−0.50). This compares to a price of US$8.40 had he/she done nothing and US$7.40 with hedging.

The put option provides a price floor (subject to basis risk) but no ceiling against the possibility of higher prices. Unfortunately, as with any insurance policy, the benefits come at a cost of the premium, which is significant. Similar futures and options market operations can be defined for a user of agricultural products as inputs into other productive activities in order to protect against unforeseen increases in input prices, say a cattle feeder who feeds corn.

Futures markets have two categories of participants: (1) hedgers – those users and producers of commodities who seek protection from price risk and (2) speculators – investors willing to accept price risk in order to make profits. Speculators in futures markets, by their availability at the time of need to assume risk, perform an important economic function: they provide liquidity.

However, in the past several years, a new class of commodity investor has emerged, the financial index investor, who has diversified his investment portfolio to include commodity investment as an asset class. By pouring billions of dollars into commodity futures markets, the concern has been raised that these institutional investors are contributing to food price inflation by creating massive bubbles in agricultural futures prices. This issue continues to be a topic of research but a number of recent studies have failed to find a direct link between index trading and agricultural futures price movements (Irwin and Sanders, 2011; Etienne *et al.*, 2013).

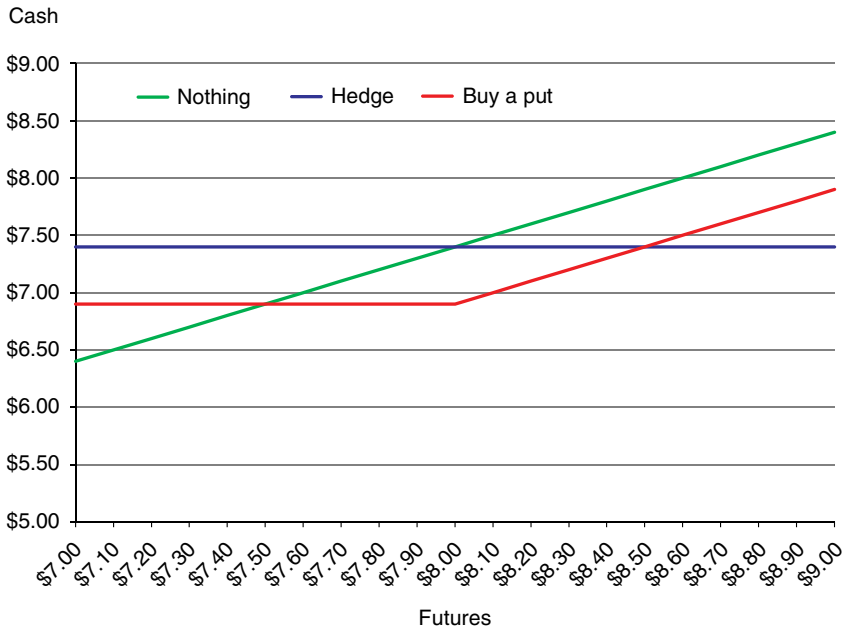

Figure 4 Net wheat returns from cash sales at harvest, hedging, and buying a put at various futures prices at option expiration.

Government Regulations on Prices

Government programs designed to influence prices of the US agricultural products have been in effect since the 1930s. Until the late 1990s, many products, including corn, cotton, wheat, barley, soybeans, milk, tobacco, wool, rice, and sugar, were subject to government programs. The motivation for such programs was to influence both the level and variability of prices within and between production cycles. Government programs in support of agriculture have historically been in the form of direct payments to producers and commodity price supports that effectively established a minimum price that producers would receive. Recently, such programs have either fallen out of favor with legislators or lost significance as commodity price levels have risen far above legislated levels of support. For example, in the 2008 farm bill, the target price for wheat (the national average price below which farmers would receive price support payments, less direct payments) was set at US$3.92 per bushel for 2008–09 and US$4.17 per bushel for 2010–12. This level of price support was below the life of contract lows of the July Kansas City wheat contracts, much less than the average price for the year (see **Figure 5**).

Another subsidy program, a federal cost-share program for crop insurance premiums, is gaining prominence as a major feature of the US farm policy. Crop insurance products that protect against both production and price risk are available, providing US producers with some degree of income security.

Efficient Price

The notion of an efficient price relates to its ability to quickly transfer new information. Thus, one would expect price in an efficient market to respond to new information in a timely manner. Notions of pricing efficiency have temporal, spatial, and form dimensions. All can be summed under the heading of 'the law of one price.' In its most simple form, it says that identical commodities should have the same price. Undoubtedly, the cost of making the commodities identical must be taken into account, so that wheat next month is not the same as wheat today – the two commodities are connected by storage. Wheat in Texas is not the same as wheat in Kansas – the two commodities are connected by transportation. And finally, wheat is not the same as bread – the two commodities are connected by processing. More directly, in an efficient market, prices reflect information such that the marginal benefits from acting on additional information are not greater than the marginal cost of acting on the information (Fama, 1970). Costs of acting on a new information signal must be taken into account when assessing the efficiency of a particular market.

This notion has been given formal treatment in terms of three forms of market efficiency: weak, semistrong, and strong. These forms focus attention on predictability of prices under particular information sets: weak form conditions on past prices (past own prices), semistrong conditions on all publicly available information, and strong form conditions on all information. Violations of weak-form and semistrong-form efficiency have been demonstrated for several agricultural commodities (Bessler and Brandt, 1992).

The law of one price (Ardeni, 1989) suggests that prices for the same commodity (similar commodities) differing only by time, space, or form will themselves tend to an equilibrium relationship. For short periods of time such prices may deviate from one another, but in the long run, they are brought back into their 'normal' equilibrium relationship with the difference reflecting the cost of making the commodities identical. Under some rather simple conditions, such prices will be cointegrated (Engle and Granger, 1987). Cointegrated prices will reflect the

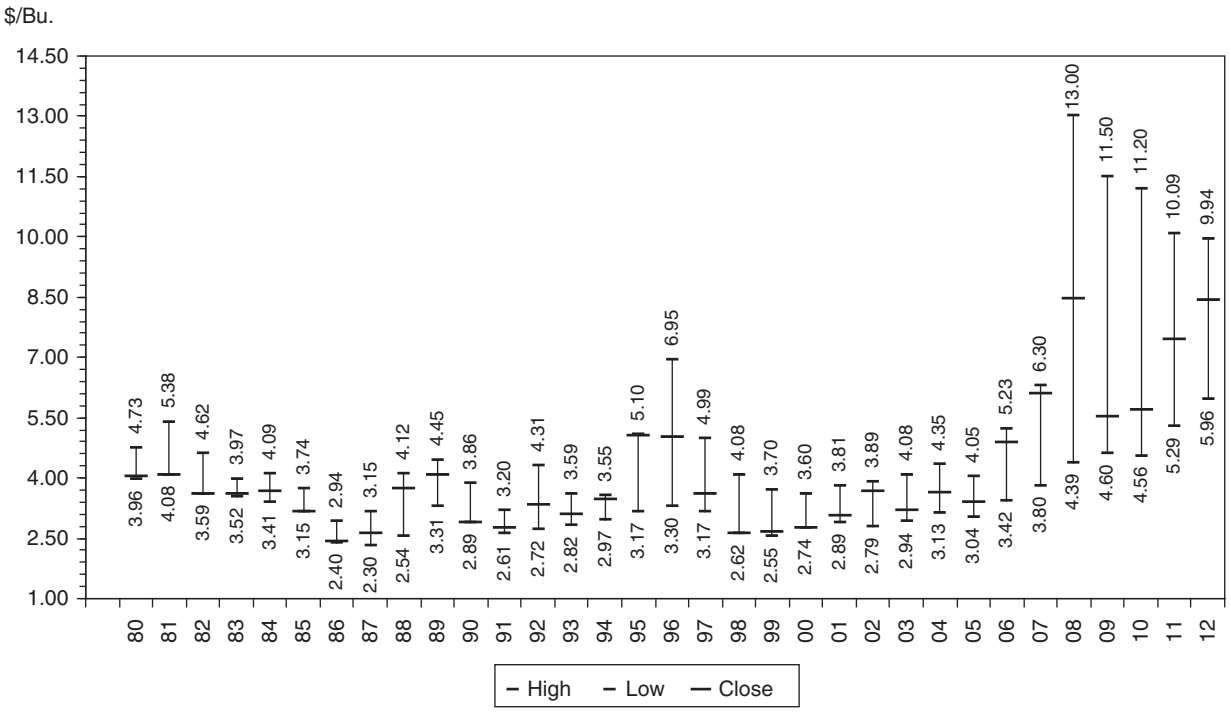

Figure 5 July Kansas City wheat prices: high, low, and close.

extent to which the market is defined. Government interventions will serve to effectively block such cointegrations by restricting the 'free flow' of information or product. Recent advances in modeling prices from markets use the notion of threshold cointegration (Blake and Fomby, 1997) to reflect that small differences in prices of commodities separated by space, time, or form may persist, as they are less than the threshold embedded in the cost of transactions.

Price Level

The foregoing discussion centers on relative prices. They are defined in terms of exchange for money (the numeraire good). The quantity of money in the economy will define the nominal level of these prices. In periods following substantial growth or contraction in the quantity of money, the price level may change quite rapidly. This is defined as a period of inflation or deflation – a period when the general price level increases or decreases. Historically, such periods have been at the heart of social and political turmoil, as witnessed by the late 1800s and the silver coinage (bimetallism) political campaign of William Jennings Bryan in the US, the hyperinflation in Germany in the 1920s, the great depression of the 1930s, and the inflation during the 1970s in the US. Each of these periods is characterized in terms of increases or decreases in the general price level. Further, each period experienced contractions (the US in the late 1800s and 1930s) or expansions (Germany in the 1920s and the US in the 1970s) in the quantity of the numeraire good (money).

The equation of exchange is helpful in understanding such periods: $MV=PQ$. Here, M is a measure of the money stock, V is a measure of the velocity of money (the number of times per unit of time that a unit of money turns over), P is a measure of the general price level (changes in the general price level are measured by broad-based price indexes such as the consumer price index or the wholesale price index), and Q is a measure of real value of transactions. For V constant and the economy at full employment (the economy is operating such that all resources are fully employed), an increase in M will result in an increase in P; decreases in M result in decreases in P. During the late nineteenth century, the US was on the gold standard. This tied the quantity of money (defined as the amount of currency and bank deposits) to the quantity of gold held by the government. From 1870 to 1896, there were few new gold discoveries to support the rapidly growing US economy. Bordo and Schwartz and Bessler (1984) argue that the relatively fixed money stocks (M) and an expanding economy (Q) had to result in either increased velocity (V) or a decrease in the price level (P), or both. In fact, Bessler provides empirical evidence that the price level actually fell in response to the contracting money supply.

A similar argument is behind explanations for the Great Depression, the inflation of the 1970s in the US, and the hyperinflations in Latin American in the mid-twentieth century.

It is generally believed that in the long run changes in money supply do not affect changes in relative prices, that is to say, the traditional view is that money is a veil, which merely covers, but is not a part of the real workings of the economy. However, recent work has at least questioned the short-run relevance of this view. Bordo (1980) discusses the short-run nonneutrality of money. Differing market institutions are offered as explanations for money showing nonneutral effects.

Agricultural products and other basic commodities (metals) are sold in auction-type markets, whereas other goods and services are often sold in posted price markets or under contracts which cover long periods of time. Pulses in the money supply will find their immediate effect in agricultural and other basic commodity market prices and show lagged (sluggish) effects throughout the rest of the economy.

Mathematical Models to Elaborate Plans for Adaptation of Rural Communities to Climate Change

JB Grau, JM Antón, D Andina, AM Tarquis, and JJ Martín, Ciudad Universitaria, Madrid, Spain

© 2014 Elsevier Inc. All rights reserved.

Glossary

Adaptation to climate change The strategies that must be adopted to make the changes in the processes, practices, and structures to moderate the potential damages or to benefit from the opportunities associated with the change.

Climate change mitigation Mitigate climate change by reducing the sources or enhancing the sinks of greenhouse gases and other factors.

Hierarchy A representation of a complex problem in a multilevel structure, whose first level is the goal followed successively by levels of factors, criteria, subcriteria, and so on down to a bottom level of alternatives.

Multicriteria decision analysis (MCDA) An activity that helps making decisions mainly in terms of choosing, ranking, or sorting the actions with the basic ingredients: finite or infinite set of actions (alternatives), at least two criteria, and at least one decision maker.

Multicriteria decision making To make decisions in the presence of multiple, usually conflicting, criteria.

Multicriteria decision methods Mathematical methods to support MCDA.

Multiobjective mathematical programming General formulation of decision problems where a set of objective functions representing different criteria have to be optimized.

Outranking methods Multicriteria methods based on pairwise comparison of actions.

Scope and Objectives

Climate change is on the policy agenda at the global level, with the aim of understanding and reducing its causes and to mitigate its consequences. As in all natural, technological, and social changes, the best prepared countries will better support their specific effects of climatic change and will recover more rapidly. Therefore, it is essential to know those areas that are more sensitive to the negative effects of climate change, the parameters to be taken into account for its evaluation, and comprehensive plans to deal with it.

The adaptation to the climate change is now in the international sphere and is discussed in this article.

The authors try to understand, like adaptation to the climate change, the strategies that must be adopted to make the changes in the processes, practices, and structures to moderate the potential damages or to benefit from the opportunities associated with the change. These strategies must contemplate all the factors intervening into the environment including the collectivities that dwell in. The costs must be evaluated and also the negative repercussions for the sustainable development that are likely to appear.

Adaptation to climate change is a natural process, but man must anticipate, analyze, and quantify it. The development of strategies and the choice of alternatives, as well as to assess the costs of adaptation plans are a must. These plans may not be the same across the globe and each plan would depend on the geographical area. However, this article is intended to develop a common methodology and models, which can be adaptive and flexible.

The aim of this article is to show mathematical models based on multicriteria decision methods that could be applied to different geographical areas. In principle, the authors focus on Latin America.

These methods support decisions making, enable to develop and evaluate integrated plans for adaptation of different communities. European and Latin American areas are particularly vulnerable to climate change. They need to take into account all the factors involved, their side effects, and the diversity of the members of the network. The models will have to take into account criteria of physical type (meteorological, soil, and water resources), for the use of soil (agricultural, livestock, forestry, mining, industrial, urban, and tourism), economic (revenues, costs, benefits, and infrastructure), social (population and decision makers), political (implementation, legislation, and votes), education (educational programs and dissemination), and environmental.

General Objective

The objective of this article is to present a mathematical model that will allow the development and evaluation of integral plans for adaptation of communities to the climate change, in vulnerable areas of Europe and Latin America and to help select the most suitable alternative, evaluate the costs and design strategies of application, formation and diffusion of knowledge, and the education of the society.

The results will lay the basis of economic and social sustainable development, by means of a suitable planning and territorial arrangements, including not only the rational and sustainable use of the Earth, but also other natural resources. One of these is water resources that needs consideration for the arrangement of the hydrographic river basins and an integral management of these resources, as much as for the superficial water as well as underground water. All this will help, without a doubt, to promote a change in the social behavior of the involved area and the interrelated ones, by means of the opportune programs of information and education.

The authors' mathematical model named 'weighted PROMETHEE' is used for the generation processes, analysis, and evaluation of strategies of adaptation to the climatic change. It is supported by the use of multicriteria methods to aid decision making, developed by members of the GASC-UPM group based on the classic ELECTRE, PROMETHEE, and Analytic Hierarchy Process (AHP) method. It will be used to elaborate a General Plan of Adaptation to Climate Change, to serve as framework for the development as Regional Plans of Adaptation to Climate Change, management of water resources, and control of desertification.

The State Of The Art

Currently in most countries, international forums and institutions, universities, and research groups are studying methods and planning for the fight against climate change and, more recently, for adaptation to climate change. This has been possible thanks to the fact that groups of researchers have been trying to convince public opinion and the institutions that they must not expend efforts in the fight against climate change and that they have to divert them to the study of adaptation to climate change. However, still the majority of studies and models that are emerging target item to resolve specific problems and to predict the behavior of natural or human factors such as the elevation of the sea level, the increase in CO_2, etc., but without obtaining a global model that could give guidelines to make decisions appropriate in time and space.

The Framework Convention of the United Nations on Climate Change (UNFCCC) has created in most countries an Observatory or Commission on climatic change that is elaborating national plans of adaptation to climate change, but always on evaluation of impact on certain factors like water resources, biodiversity, the level of the sea, ozone layer, etc., without including any model like the one that is set out in this article (see European Commission, 2008; United Nations, 1992; Green Book (UE), 2007; Dresden, 2011).

The UNFCCC has organized annual conferences. In the last one (COP 15 – Copenhagen 2009, COP 16 – Cancun 2010, COP 17 – Durban 2011, COP 18 – Doha 2012, and COP 19 – Bonn 2013) only intention agreements have been obtained, but no imperative actions.

The Intergovernmental Panel on Climate Change was established in 1988 by the World Meteorological Organization and the United Nations Environment Program (UNEP). It has presented several reports about the causes and consequences of climate change but without an integral approach for adaptation.

Multicriteria analysis for climate change (MCA4climate) is a major new UNEP initiative providing practical assistance to governments in preparing their climate change mitigation and adaptation strategies (UNEP, 2011). It is designed to help governments, particularly in developing countries to identify policies and measures that are of low cost, environmentally effective, and consistent with national development goals. Many developing countries are still at an early stage of developing formal climate change policy plans and identifying specific nationally appropriate mitigation actions and national adaptation plans and actions.

This is a challenge for multicriteria decision analysis (MCDA). The principal way in which MCA4climate seeks to assist governments is through the application of the MCA4-climate policy evaluation framework – a powerful step-by-step analytical tool that has been developed by UNEP with assistance from international experts. This framework is based on a multicriteria analysis (MCA) approach – a well-established technique for identifying multiple impacts and aiding decision making. It ensures that the different dimensions of climate policies, including those that cannot be easily measured in monetary terms are taken into consideration. It also facilitates the engagement of stakeholders in the policy-planning process. Three case studies – Mumbai (in India), South Africa, and Sana'a Basin (in Yemen) – were carried out in order to demonstrate the practicalities of applying the framework.

The well-known Kyoto Protocol, not yet signed by all important countries, is focused, only to reduce CO_2 emissions.

There are organizations like Oxfam doing basic reports directed at the controversy on who causes CO_2 emissions and who has to pay the cost of reducing it, rich countries or poor countries. With the results of this article it will be possible to put in evidence affirmations interested or erroneous as well as to provide a greater social support on the proposed solutions (Oxfam, 2007).

The Forums of the Earth, also called UN Conference on Environment and Development, were held in Stockholm (Sweden) in 1972, Rio de Janeiro (Brazil) in 1992, and Johannesburg (South Africa) in 2002.

In the Rio Conference (Conference on Environment and Development, 1992) the participating countries agreed to adopt a development approach to protect the environment while ensuring economic and social development. At this summit, various documents were approved by 178 governments, which are as follows:

- Program 21: This is an action plan which aims at environmental and development goals in the twenty-first century.
- Rio Declaration on Environment and Development: Defining the rights and duties of States.
- Statement of principles on forests.
- Convention on Climate Change, Biodiversity, and Desertification.

The Earth Summit +5 took place in a Special Session of the General Assembly in 1997. The main objective was to analyze the implementation of Agenda 21 adopted at the Summit of 1992. After intense debate due to differences among States on how to finance sustainable development at the global level, various agreements were obtained, which were reflected in the final document of the session. These agreements are the following:

- To adopt legally binding targets for reducing emissions of greenhouse gases which are causing climate change.
- Move more vigorously toward sustainable patterns of production, distribution, and use of energy.
- Focus on poverty eradication as a prerequisite for sustainable development.

The World Summit on Sustainable Development, also known as the Johannesburg Summit (2002), was a follow up to Agenda 21 and its main objective was the adoption of specific commitments in relation to Agenda 21 and achieving sustainable development.

During 2001 a series of national consultations and preparatory meetings by regional and subregional organizations were conducted to assess the opportunities and challenges posed by sustainable development and to establish priorities, initiatives, and commitments needed to achieve this development.

The intergovernmental program was the central part of the summit, but attention was also paid to all sectors of the population who are committed to sustainable development, including those defined in Agenda 21, namely enterprise and industry, children and youth, farmers, indigenous people, local authorities, nongovernmental organizations, scientific and technological communities, women, workers, and unions.

Most countries, like Peru, are preparing National Plans for Climate Change adaptation and Risks management in Agricultural Sector (PLANGRACC) (see Agricultura Perú, Ministerio, 2011).

Methodology

The framework is based on a MCA approach that is a well-established technique for aiding decision making and it has already been successfully deployed in many areas of policy-making for the authors and other experts. The methodology uses a practical step-by-step tool for identifying and prioritizing mitigation and adaptation policies that are consistent with developmental goals. It ensures that all the different dimensions of climate policies, including those that cannot be easily measured in monetary terms, are taken into consideration. It also facilitates the engagement of stakeholders in the policy-planning process.

To test the models and to provide inputs to the general model, four case studies have been included.

Several steps have been established:

- To establish a consortium among mainly Research Groups of Europe and the Latin American countries to establish synergies that allow to obtain a common approach to develop and maintain the models.
- To create a climatological, edaphic, economic, sociological database, common for all the members, in compatible formats and scales to elaborate the initial matrix (IM).
- To analyze the present situation of the country members of the consortium in relation to the impacts of climate change, the battle against erosion and the management of water resources, and to forecast future scenes of climate change.
- To integrate in the model those models already made for erosion and desertification and those of integral management of water resources and planning, arrangement of hydrographic river basins, and urban waste management.
- To model the incidences of the possible solutions adopted in other areas with and without performance plans.
- To design and to reproduce material on the causes and effects of climatic change, incorporating the results of the project, to be distributed between local institutions and schools.
- To study the incidence that the project results will have in an improvement in the environment and with climatic change, education, sanitary improvement, and in the fight against poverty.
- To analyze the incidence that the integration of the society may have in the plans proposed by means of suitable campaigns of information, education, etc.
- To define case studies in relation to mitigation and adaptation actions to test different elements of the framework and to consider that the lessons learnt will be useful to the development of the overall model.
- To integrate the results of investigations made by the members of the partnership via a common model that will reduce costs, avoid duplications, enrich the knowledge, and make possible the development of the communities involved.

The actual 'climatic change,' activated more rapidly by emissions caused by humans, could have important effects on different countries that have diverse soils, populations, and use of lands. Let us consider a region that will support effects, maybe unfavorable with increase of temperature and decrease on rain. It is expected to require planning to change the actual status for adaptation to new situation or to mitigate its effects. For example, the change of use of lands can be made in different ways. In this case, the use of MCDA is required. The authors' experiences on multicriteria decision methods (MCDAM) and the application of some of these methods, in relation with climate change, are shown as cases studies located below. Some of the MCDAM, selected and used by authors, will be presented now in their main lines.

Multicriteria Decision Methods

MCDAM are models to aid decision making when there is a situation with several alternatives that should be optimized with respect to some criteria. The first thing to do, when applying a multicriteria approach to a project, is to analyze the feasible alternatives that exist. Then set the criteria and pseudocriteria and finally adopt the normalized weights that meet the decision maker preferences.

One criterion is used to discern if an alternative is at least as good as another to the decision maker. Usually, it is expressed by a value higher than zero. A criterion is called a pseudocriterion when the difference between the utility functions is higher than zero but small we cannot say that the alternative higher for that criterion preferred. Thresholds are involved here.

Pseudocriteria concept is widely used in the outranking methods. Preference threshold p and indifference threshold q are introduced for each criterion. They help the decision maker to show the preferences between alternatives.

The MCDAM can be continuous if the number of alternatives is infinite, with continuous functions to optimize and restrictions. When the number of alternatives and criteria are finite and generally small in number, the methods used are the discrete ones and within them, we have the outranking methods. They are based on knowing whether an alternative

dominates another or not. One should know if in relation to a criterion, an alternative is, at least, as good as another.

Following, the IM is elaborated. It is also called decisional matrix. It is a matrix formed by alternatives in rows and criteria in columns. They shall show utilities as positive numbers and a file will be added below with the weights of the standard criteria (sum 1) and another with the indexes, that will be $(+1)$ if that criterion is of the kind 'more is better' and (-1) if it is of the kind 'more is worse.'

Discrete Multicriteria Decision Methods are used in this article. The most important are the outranking methods. They consist of a compromise between the too poor dominance relation and the excessive ones generated by utility functions. The most significant methods in this area are ELECTRE due to B. Roy, PROMETHEE presented by Brans, and AHP by Saaty.

ELECTRE method

It is due to B. Roy, who in 1985 published 'Méthodologie multicritère d'Aide à la Décision' in the journal *Economica*. It is an acronym for Elimination Etchoix Traduisant la Realité. From that date Roy and his disciples were improving and getting new versions of the method ELECTRE I, they are II, III, IV, V, VI, and Tri. It is an outranking method that is based on the concepts of concordance and discordance. A threshold concept is introduced. Roy's team has developed in Paris an application software, although MATHCAD or other programs such as MATLAB or MAPLE can also be programmed for this use.

Standardized weights are applied to the criteria for setting decision-maker preferences. Dominance relations are put into a graph and alternatives that are not dominated and dominating others are included in the core. From these data, following the proposition (Roy, 1985), an alternative i outranks the alternative k, i.e., ELECTRE preferable to it, if two concordance and discordance conditions are both satisfied. For the first a concordance matrix should be obtained, from a decisional matrix 'standardized and weighted.' To consider discordance, a discordance matrix is also obtained.

PROMETHEE method

PROMETHEE methods are a family of Discrete Multicriteria Decision Aiding inside of the well-known outranking methods. J.P. Brans, professor at the University of Brussels, presented the PROMETHEE I and II methods in 1982. Brans and Vincke (1985) published an important paper on these methods. These methods are referred to as 'Initial PROMETHEE.' Brans and other authors added new methods to this family. One of them is named by the authors as 'Weighted PROMETHEE.' Brans, Vincke, and B. Mareschal published papers, a few years later and developed PROMETHEE III (ranking based on intervals) and IV (continuous case), and a software called PROMCALC and later PROMETHEE-GAIA and Visual PROMETHEE (Brans *et al.*, 1986; Brans and Mareschal, 1992a, 1994, 2002). In 1992 and 1994, Brans and Mareschal suggested PROMETHEE V (MCDA including segmentation constraints) and PROMETHEE VI (representation of the human brain) (Brans and Mareschal, 1992b, 1995). Other authors followed adding new methods to this family (Figueira *et al.*, 2004; Corrente *et al.*, 2013; Mousseau *et al.*, 2000). The most known and applied of PROMETHEE Methods are PROMETHEE I and II.

PROMETHEE is an acronym for Preference Ranking Organization Method for Enrichment Evaluation.

They used the concept of pseudocriterion as B. Roy and defined six types of pseudocriterion: type I: the usual, type II: quasicriterion, type III: with linear preference, type IV: level or in stairs, type V: with linear preference and indifference area and type VI: Gaussian.

They define a preference index. This index gives a measure of the preference of one alternative over other for all the criteria. From these indexes outgoing and incoming flows are defined. The outgoing flow is a measure of the dominance of one alternative over other. The incoming flow is the measure of how much that alternative is dominated.

The results in form named PROMETHEE I give a partial preorder from outgoing flow and ingoing flow, and in form PROMETHEE II a total order from the total flow that is the difference from both, outgoing minus ingoing.

The PROMETHEE III, IV, V, and VI, weighted, Tri, Cluster, etc. have other characteristics and applications. For example, V considers alternatives with restrictions and the weighted used weights, as done in this study.

Analytic hierarchy process method

It was presented by Saaty (1980). It is based on pairwise comparisons. It establishes three levels of comparison: the objective, alternatives, and criteria levels. It gets total weights and the heaviest alternative is preferred. The Saaty group has developed an excellent software, called Expert Choice, used in the Section Case Studies.

Case Studies

To obtain the inputs for the integral model the authors have studied different actions that have a high influence in climate change.

Territorial Planning in La Colacha River Basin (Córdoba Province, Argentina)

Introduction

Agriculture in developed countries must take into account food production, profitability, as well as environmental impacts. Environmental impact assessment covers infrastructure investment. Its integration in the decision-making process makes it an important environmental policy tool for influencing the location of projects. The river basin management plans will require coordination of all measures aimed at water protection including designation of catchment areas subject to or vulnerable to pollution from nutrients. To aid decision makers to adopt the best river basin management plans, the discrete multicriteria decision methods appear to be the most appropriate. La Colacha is a subbasin at the south of Arroyos Menores basin of Rio Cuarto city, formed by the junction of La Colacha and El Cipion streams, both being tributary of Santa Catalina stream (see **Figure 1**).

It includes an area of 416 km^2, which ranges between altitudes of 560 and 1000 m above sea level. The monsoon rainfall is on average at 830 mm $year^{-1}$, and is concentrated between October and April. The use of the land is mainly

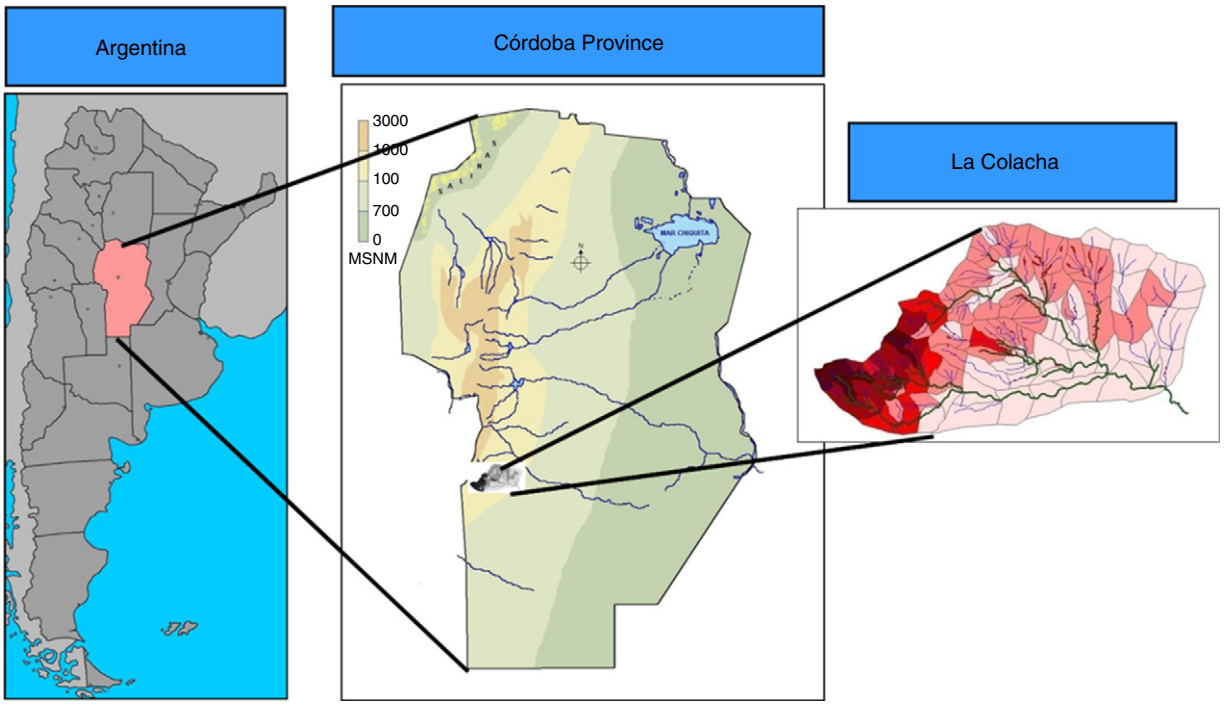

Figure 1 La Colacha basin in Argentina.

Figure 2 Gullies ('*cárcavas*') in La Colacha.

agricultural–livestock farming on the plains and extensive farming along the mountain ranges. The main degradation processes are the hydrologic erosion originating in furrows and with big gullies or ditches ('*cárcavas*') (see Figure 2), erosion in permanent rivers, and sediments being carried down to the lower basin areas.

Alternatives

Twelve alternatives (see Table 1) have been selected from the following combinations:

1. Land use.
   - Agrosilvopastoral use (ASP).
   - Actual soil use (ACT).
   - Intensive agricultural use (INT).
2. Soil conservation practices (SC): Use of techniques for erosion control and to reduce water pollution (terraces and filter strips).
3. River basin actions (HM): To reduce flooding, sediment, and contaminant load and avoid ditch and stream erosion.

Table 1 Twelve alternatives for La Colacha

No.	*Alternatives*	*Description*
1	ASP	Agrosilvopastrol use
2	ASP + SC	ASP with SC
3	ASP + HM	ASP with HM
4	ASP + SC + HM	ASP with SC and HM
5	ACT	Actual use (*status quo*)
6	ACT + SC	ACT with SC
7	ACT + HM	ACT with HM
8	ACT + SC + HM	ACT with SC and HM
9	INT	Intensive use (soybean)
10	INT + SC	INT with SC
11	INT + HM	INT with HM
12	INT + SC + HM	INT with SC and HM

Abbreviations: ACT, actual soil use; ASP, agrosilvopastoral use; HM, river basin actions; INT, intensive agricultural use; SC, soil conservation practices.

Criteria

Thirteen criteria and its respective weights have been applied to the 12 alternatives as follows:

- Field research,
- Expert panels,

- Social investigation, and
- Personal interviews.

The consequences of the alternatives would be felt from different points of view conducting to the adoption of the following criteria, that are enough independent, and that include all the possible effects. Their relative importance will be considered in discrete MCDM by setting sets of weights. Some criteria will get valuations from measures with units, and others are qualitative, and will get a qualifying index (*qi.*) of valuation in the range (1–10) of the kind 'more is better' as elicited by authors from their experience. All the criteria have indices I_j elements of a vector I, being $I_j=1$ if the criterion j is taken of the kind 'more is better' and being $I_j=-1$ if it is of the kind 'more is worse.'

Environmental criteria

1. Peak runoff (PRU), in $m^3\ s^{-1}$, is the maximum runoff of a basin for 80 mm rain in 6 h, that has an approximately 25 years return period, of the kind 'more is worse.' Runoffs were estimated with a model HEC-HMS (USACE (US Army Corp of Engineers), 2009). To estimate alternatively a basic winter volume of flow was found too imprecise and hence that different criterion was not used.
2. Average annual erosion (ERO), being the mean expected annual soil loss, in Mg ha^{-1} $year^{-1}$, assesses the sustainability of the use of soil with an alternative; hill-slope erosion. It is an indicator of long-term soil productivity and quality (Agrell *et al.*, 2004; Antoine *et al.*, 1997; Lakshminarayan *et al.*, 1995). The authors used RUSLE 2 (USDA-ARS, 2009) to estimate it, with aids for gullies such as by Dabney *et al.* (2008). It is of the kind 'more is worse.'
3. Sediment delivery (SED), in thousands of Mg (metric tons), indicates soil losses getting into a permanent stream, containing also pollutants, of the kind 'more is worse.' This was estimated using modified universal soil loss equation model (MUSLE model) (Williams, 1975), also for deposits in filter strips with (Muñoz-Carpena and Parsons, 2005). Measured differently from ERO.
4. Index of Environmental Quality (CAM), is in (qi.) range, of the kind 'more is better,' derived in the ways of Gómez Orea (1999), by considering the percentage of area for pasture, the percentage for agriculture, diversity in the types of vegetation, characteristics of streams, biodiversity, scenic attributes of landscape, margins and corridors with trees. This is adapted to be used to compare alternatives, not to compare basins.

Economic criteria

1. Investment (INV), in millions of argentine pesos (ARS). It is of the kind 'more is worse,' deduced from the cost of possible actuations in the subbasin. It was transformed into an annuity in standard ways, not differentiating between public and private sources. The opportunity cost under Argentine conditions was taken as 12%.
2. Maintenance (MAN), in millions of ARS $year^{-1}$, of the kind 'more is worse,' being the annual cost for reparation of works and rural roads, and estimated for roads with peak runoff (De Prada *et al.*, 1994).
3. Loss of agrosurface is the percentage of the agrosurface, of the kind 'more is worse,' estimated from HEC-HMS and VFSMOD (Muñoz-Carpena and Parsons, 2005). It is an important concept for such good large agrolands.
4. Benefits (BEN), in ARS ha^{-1} $year^{-1}$, being private and short term, of the kind 'more is better,' from the margin in a typical exploitation (De Prada *et al.*, 2008). The crop-weighted gross margin and the cost values were considered at 2010 prices. A monoculture may increment BEN and degrade more soil, but it influences farmers' decisions (Groot *et al.*, 2007; Gil *et al.*, 2008).

Social criteria

1. Ease for implementation (FIM), of the kind 'more is worse' for the MCDM in this article, is taken as the 'time needed for actions' (Degioanni *et al.*, 2000); sometimes indicated otherwise in the form of an (id.) as in Grau *et al.*, (2008, 2009), Anton *et al.* (2010), or otherwise as in Gonçalvez *et al.* (2007).
2. Externalities (EXT), of the kind 'more is worse,' are the effects of agriculture in other ecosystems, mainly caused from erosion of water from plots and used for multicriteria studies (De Prada *et al.*, 2008; Paneque Salgado *et al.*, 2006), effects on wetlands below (Cantero *et al.*, 1998; De Prada and Penna, 2009), and on roads (Cristeche, 2009).
3. Social acceptability (ACE) is necessary for regional planning, (e.g., see Zhen *et al.*, 2007), and includes sensibility to environment effects such as in Smith and McDonald, (1998) and considers remediation techniques (Gil *et al.*, 2008), as measured in Grau *et al.* (2008, 2009) with a valuation of 'more is better' scale as (*qi.*) in the range (1–10).
4. Employment impact (EMP), as measured by the number of jobs generated by the alternative. This is a principal social criterion and considered of the kind 'more is better.' The employment estimates considered the labor requirements of each crop rotation and forestation. This was used similarly with multicriteria in Grau *et al.* (2008, 2009), Simonovic and Akter (2006), and Paneque Salgado *et al.* (2006). This was estimated following Llach *et al.* (2004), depending on the type of activity and on the yields of the crops.
5. Legislation in force (LEG) is to be in accordance with adopting the solutions in an alternative, and it was measured by a valuation (*qi.*) in the range (1–10) 'more is better' scale. The *status-quo* alternative ACT is well for LEG, and actually INT is also well. The conservation of soils is backed by law (Law 8359, Arg., for conservation of soils), but action is voluntary and scarce (Cristeche, 2009). The alternative ASP when shifting from farming to forest has legal difficulties, and also hydraulic management often needs expropriation of lands.

Multicriteria methods applied

The following discrete MCDM have been applied:

- ELECTRE I, see Roy (1985), Roy and Bouyssou (1993).
- For initial PROMETHEE, see Brans and Vincke (1985), Brans *et al.* (1986); from it is derived the adopted weighted PROMETHEE, which seems preferable to introduce indication of relative importance of criteria, for it see Brans and

Mareschal (1994); it has been used previously by authors, see Anton *et al.* (2006, 2010) and Grau *et al.* (2008, 2009).
- AHP, see Saaty (1980, 1996a,b).

Initial matrix

Following the studies to prepare the doctoral thesis (Cisneros, 2010), the authors have the IM (see **Table 2**).

Systems of weights

The methods ELECTRE and weighted PROMETHEE depend on the weights for the respective criteria by elicitation using experience (Grau *et al.*, 2010). There is some literature on the methods to obtain these elicitations and some of them are used also in common software, but that requires comparing for calibration with other well-confirmed valuations of results, which were inexistent here. Three sets of weights that are given in **Table 2** have been used:

1. Based on an entropy method as in Zeleny (1982), Barba-Romero and Pomerol (1997), and Zhen *et al.* (2007). They were deduced from the IM of **Table 2**. The authors did a comparison, in a precedent case, with elicited weights and have felt that the resulting weights did not change essentially. These weights result were favorable for the environment criteria; they were used considering an 'environment trend.'
2. Based on equilibrium, all the criteria have similar weights, $1/13 = 0.77$ (or 0.769230…) in **Table 2**. These weights are in comparison more favorable for social criteria, they were used considering a 'social trend.'
3. Compromised for economy, is influenced by the fact that the farmer follows mainly that trend (Gil *et al.*, 2008), giving more weight to benefits, and eliciting the others as in **Table 2**. They were used considering an 'economic trend.'

In **Table 2**, the weights with entropy are oriented for environment, the weights inclined for benefits are more of economic kind, and with equivalent weights the trend is toward considering social effects. All these weights were already normalized so as to get one.

ELECTRE method

For La Colacha with ELECTRE does not get complete classifications and the alternative ASP + SC + HM is best for environmental and for social weights. After that is the ACT + SC + HM, but economic weights give preference for INT + SC + HM and for lower thresholds also to INT + SC, and for equilibrium weights other alternatives enter, ASP + SC and for lower thresholds ASP + HM and INT + SC. All the alternatives in kernels have some SC or HM. The graph and Kernel are shown in **Figure 3**.

PROMETHEE methods

When using MCDAM for these study areas the authors use different criteria and different weights. Hence, the results are more with weighted PROMETHEE than with nonweighted ones.

In **Figure 4** the results obtained using Weighted PROMETHEE I and II programmed by MATHCAD is shown. With Weighted PROMETHEE II the alternative 6 (ACT + SC) has a maximum total flux of 0.839, i.e., it is preferred.

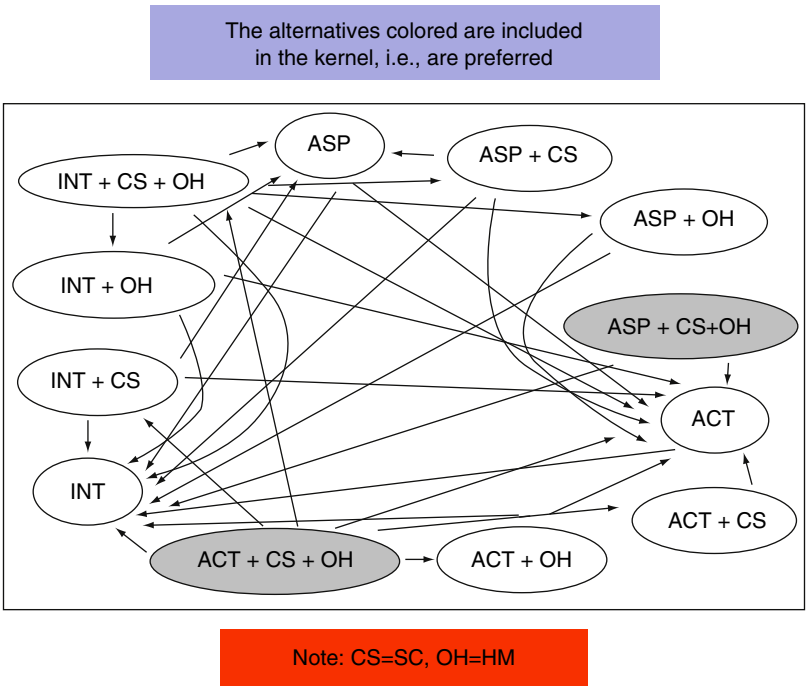

Figure 3 Graph and kernel (ELECTRE) for La Colacha. ACT, actual soil use; ASP, agro-silvo-pastoral use; HM, river basin actions; INT, intensive agricultural use; SC, soil conservation practices.

In Figure 5 the results obtained using Initial Brans PROMETHEE II programmed by MATHCAD are shown.

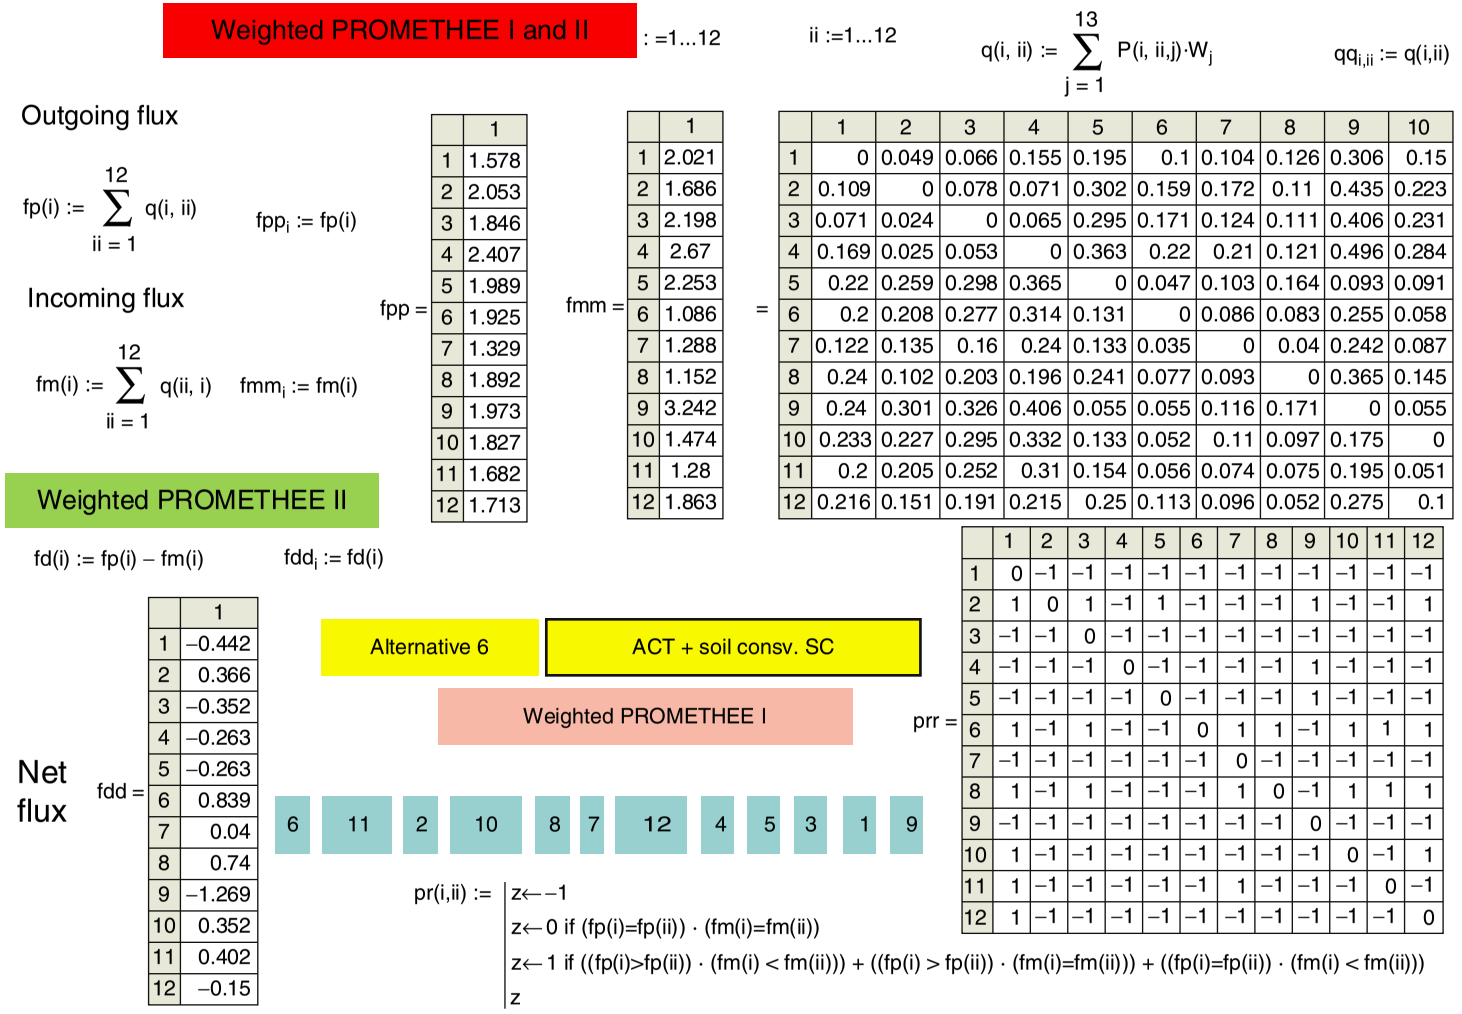
In Figure 6 the results obtained using Brans Initial PROMETHEE I programmed with MATHCAD8PRO are shown. A partial preorder has been obtained and the alternative 6, 2, and 4 are incomparable but 6 dominates more and it would be preferred.

Analytic hierarchy process method

The authors have used the Expert Choice PC software, by introducing pairwise comparisons of the criteria with relative considerations as for the weights of Table 2. In Figure 7, the EXPERT CHOICE graphical interface shows the results.

It can be seen from Figure 7 that the alternative 4 (ASP + SC + HM) is the preferred one.

Conclusions



A combined extract from these results with discrete multicriteria methods is given in Table 3.

There are some variations with methods or with trends through systems of weights, but in general the SC and the actions for Hydraulic Management HM are recommended together, and if only one SC enters before HM. Moreover, the weighted PROMETHEE method is favorable to ACT, and the ELECTRE also, but more to ASP or INT depending more on weights due to the effect of discordances. The authors found ELECTRE better for the present studies, but the results of weighted PROMETHEE are in a more clear form, for every alternative, as in Figure 4 that includes results obtained with MATHCAD. The results of the different AHP are compatible with the adaptation from the IM used in the other methods as an indication to assess preference levels for pairwise comparisons about the criteria, and it gives comprehensive graphic results as in Figure 7 favorable for environmental criteria. With the weights with the trend for Economy the alternatives with INT become more important, but not with all methods.

The examination of such tradeoffs indicates that the alternative ACT + SC + HM is more efficient as being preferable for almost all the criteria, and that the alternatives ASP and INT are differently less efficient. These comparisons are best expressed using the discrete MCDAM to get influence of all the criteria.

The authors have considered in the studies the effects of changes in alternatives for plots, naming them tradeoffs and obtaining numerically various results, which is commented as:

1. A total change from ACT to INT would deteriorate all environmental criteria variables, some 15% in PRU, 26% in ERO and CAM, and 44% in SED, increasing costs included in INV and in MAN, the cost of maintaining roads in 44%, the offer of agrolands up to 60%, and the income of land operators in 18%. In social criteria, EXT would worsen by 16%, also LEG and EMP through a more mechanized production.
2. Changing from ACT use of soil to ASP improves the environment and social criteria variables at a serious cost in economic variables, reducing favorably (PRU, ERO, and SED) and increasing the CAM index. That would require high INV and MAN, the loss of many hectares of agrosurface and of some BEN. The EXT would be reduced in good sense the employment, EMP would increase considerably.
3. Changing ACT to ACT + SC, making soil conservation works maintaining actual use of lands, will ameliorate

Figure 5 Results with Brans Initial PROMETHEE II methods for La Colacha.

environment variables, much (SED and ERO) and less (PRU and CAM). In economic variables the costs INV and MAN would increase much, ameliorating a little BEN through lesser losses of soil and water. In social criteria, EXT would be favorably reduced, the farmers would be against the change but the society would appreciate it ameliorating ACE criteria. Concerning LEG there is a law promoting this change, but that action depends on the will on land owners, and they have very few adhered to it.

4. The change from ACT to ACT + HM, affecting hydrological management maintaining actual use of lands, would require public investment in agro-infrastructure engineering, protection of streams, permanent or transitory, and rehabilitation of wetlands, mostly by microdams. That will ameliorate environmental criteria variables (SED, ERO, PRU, and CAM), the HM works being more efficient than the SC ones in reducing PRU and SED and less ERO and CAM. The HM requires severely higher INV and MAN than SC, and would have (if setting only microdams and no irrigation that is not evident here) no effect on BEN. In social values, EXT would increase more than with CS and also EMP at little values.
5. With both CS and HM effectuated, all the environmental values would increase, (SED, ERO, PRU, and CAM) at big costs, INV and MAN, increasing a bit BEN. That would cause problems with FIM and LEG criteria as the solution is complicated and with different acceptations ACE and requiring use of all natural resources of basin and mixed private and public action.

Election of Water Resources Management Entity

Introduction

In the twenty-first century, water resources (WR) are one of the top priorities worldwide. This is not only due to the need of this element for each one of the society sectors (agriculture, industry, residential use, etc.) but also due to its great variability in time and space. The consequences of the lack, as well as the excess can be dangerous, as the loss of productions by catastrophic floods and landslides. Besides, water pollution due to uncontrolled drainages carries out strong consequences for people's health, and also for the extinction of the natural habitat and the environmental risks.

In most countries, the worry for the knowledge of the existent WR and its integral dealing has recently started within four fields: (1) The transformation into irrigable land, of huge extensions of dry land, due to a bigger demand of agriculture products, (2) the usage of water for leisure and tourism purposes, as in large areas where water was not used, the population has increased strongly by a factor of 10, having installed golf courses, tourist, and residential areas, (3) bigger concerns

about environmental issues, and (4) the mass-media pressure that derives from climate change.

For all that, new laws and rules for surface water and groundwater are coming up, as well as the creation of organism to watch, standardize, and manage the water resource use. However, there is a problem that it is not always easy to deal with, as the competences are spread and in many cases are confronted, being more important political and competence subjects than rational, technical, and economic.

In Valencia (Spain), 'El Tribunal de las Aguas' ('The Water Jury') exists for more than 500 years, functioning as a model that is unique in the world. This model cannot be exported to other parts of the world due to the international intercommunity relationships. In the limit one should have a special entity worldwide that could cope with all the competences and to delegate some of them to other national entities. The ideal is not reachable, but we must arrive as close as possible and we will minimize the distance. A model needs to be found that can be adapted to the characteristics of each area (see Grau, 2003; Romero, 1993).

The Salta Province covers 155 000 km^2 and has a population of 1 million. It is in the North West of Argentina (NOA), having latitudes around 25° S. It has rain from 400 to 800 mm $year^{-1}$ (with peaks of 1200 in high altitude places in SW) and great ranges of altitude (at NE are areas at 200 m and at NW a PUNA region with summits higher than 6000 m. It has a low density of population in small cities located in important long mountain valleys, and has low standards for roads and an environment that is 'deteriorating progressively.'

The Bermejo River is the most important fluvial artery in the area. The majority and the more important rivers flowing out of the Paraná drain through this region, such as Pilcomayo, San Francisco that flows into Bermejo, Juramento, or Salado. The Horcones and the rest like Itiyuro, Rio Seco, Dorado, Del Valle streams, etc., have less water but very important for the Province, end in marshlands, generating wet areas. The lack of water is a characteristic of the whole region. Rainfall is concentrated in the summer time. The rainfall presents a strong fall, from 1200 mm $year^{-1}$ in the east to 300 mm in the Southwest. In the Northeast it goes up to 1200 mm. The groundwater resources are poor in volume and quality (salty and with arsenic). It is possible to find good quality groundwater but at deep levels (100 m) with high operating costs.

Water is the most critical factor, as much for human and animal consumption, as for the production system in general. For that reason, it is so important to define an official entity for managing the WR, in order to consider all the aspects related with data control and water management since its capture till it is used, as well as those in relation to the social, cultural, and

economic substratum, where they must be applied. The management of water must include both the surface water and groundwater. An effort should be made in seeking the best way of extraction and usage in low cost and to implement good management and the best practices.

Multicriteria methods applied

Alternatives, criteria, and initial matrix

The data that were included in our IM were obtained from the conclusions of meetings held in Salta (Argentine) in 2004. Following those conclusions five alternatives were finally selected: Public Entity, Institute, Foundation, Cooperative, and Private Company. Besides, five criteria were considered relevant: Implementation Facility, Implementation Delay, Legislation in Force, Social Acceptance, and Flexibility. To fix the weights two expert commissions were created. The order of preferences given was different and more meetings were needed to fix them. In September 2007, the authors obtained the following weights and the filled decisional matrix is shown in **Table 4** (Antón *et al.*, 2003; Anton *et al.*, 2004; Jamshidi *et al.*, 2003; Keeney and Raiffa, 1976; Zeleny, 1982; Yu, 1985; Antón *et al.*, 2007; Munda, 1995). The criteria were rated on a 1–10 scale, according to local evaluations, and other methods of elicitation except implementation delay.

ELECTRE I method

In the first place, the ELECTRE I Method is applied with the MATHCAD program (see **Figures 8–10**). In these figures, the Decisional Matrix, standardized weights, indexes, concordance matrix, discordance matrix, concordance and discordance thresholds, and the aggregated dominance matrix are shown.

Table 4 Initial matrix

		Criteria				
		1 Implementation facility (qi.)	*2 Implementation delay (days)*	*3 Legislation in force (qi.)*	*4 Social acceptance (qi.)*	*5 Flexibility (qi.)*
Alternatives	1 Public entity	8	12	10	5	5
	2 Institute	7	18	8	6	6
	3 Foundation	6	18	7	7	7
	4 Cooperative	7	20	7	8	8
	5 Private company	6	15	5	4	9
Weights (adding 1)		0.30	0.10	0.15	0.20	0.25
Indexes		+1	−1	+1	+1	+1

Note: +1 is 'more is better' and −1 is 'more is worst'.

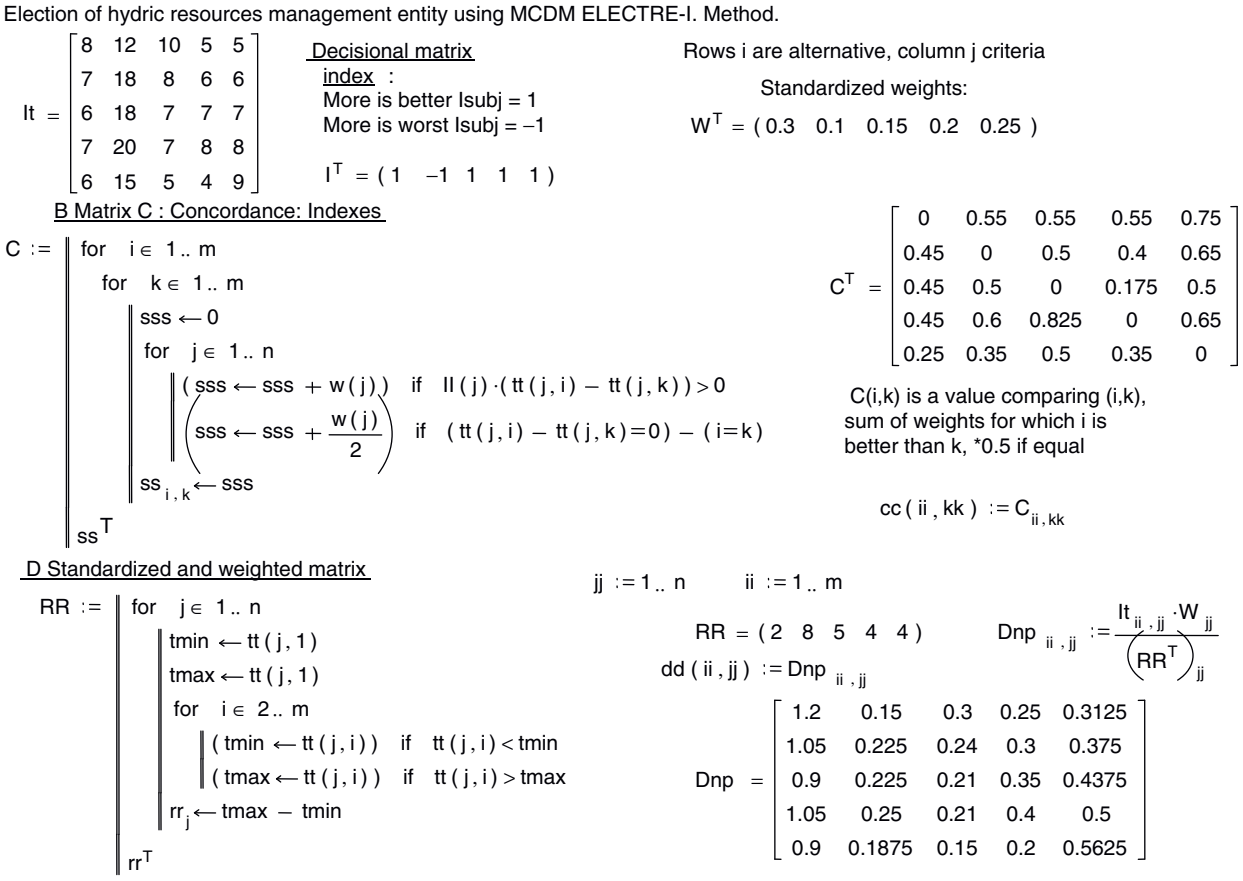

Figure 8 ELECTRE I with MATHCAD (part 1).

Finally, the Public Entity and the Cooperative are in the kernel. For that, both are preferred, but at the same level.

Analytic hierarchy process method

The results, obtained using the AHP Method, are shown in Table 5. It can be seen that the higher global weight is 0.2166903, i.e., the Cooperative is obtained as the first option.

PROMETHEE methods

Following Brans and Vincke (1985) the results in Table 6 are obtained. With PROMETHEE II the higher Phi (Net flux) corresponds to Cooperative, i.e., Cooperative Alternative is preferred. With PROMETHEE I Public Entity and Cooperative are incomparable.

Using the MATHCAD program, the results for weighted PROMETHEE in Figure 11 are obtained.

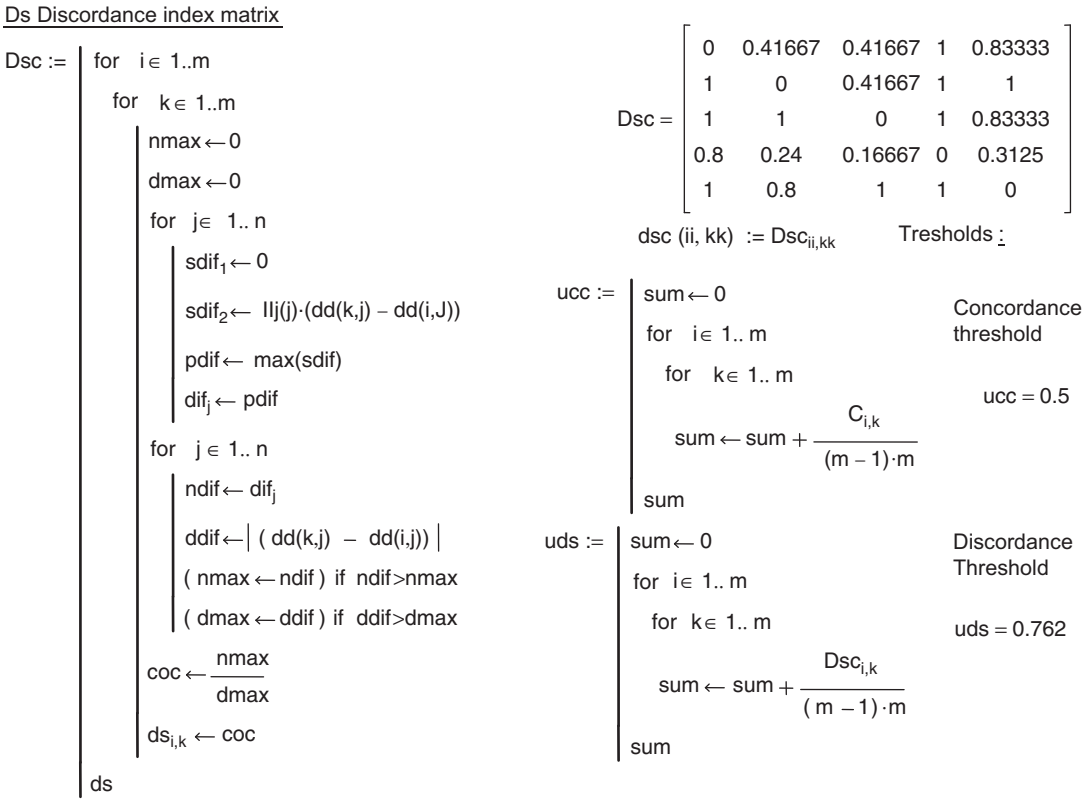

Figure 9 ELECTRE I with MATHCAD (part 2).

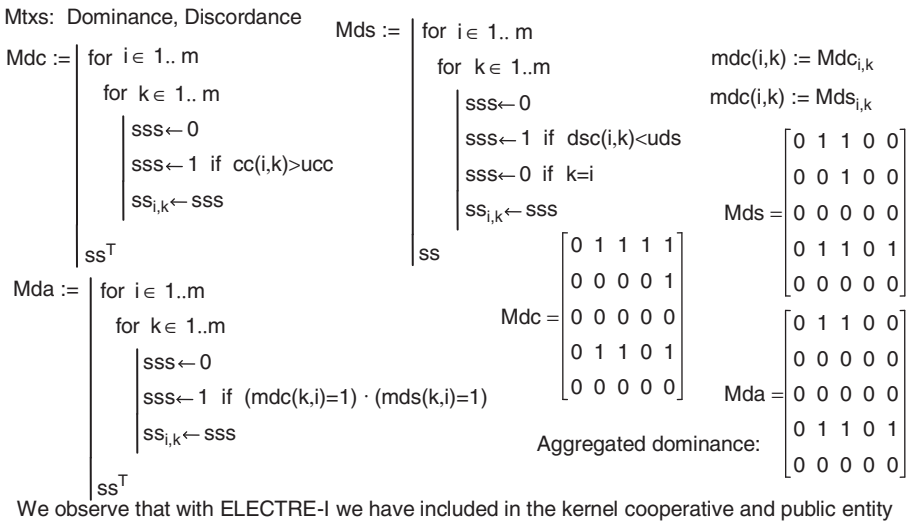

Figure 10 ELECTRE I with MATHCAD (part 3).

Considering the future situation

The authors now consider the result of the decision taken in the present situation (n) and that derived of the decision that should be taken in a fixed future step ($n+1$). It is started with initial decisional matrix (see Table 4). Normally, 25 years is taken as fix future step.

Probabilities

The probabilities associated with the change of the data indicated in the initial decisional matrix are shown in Table 7. The first number is the probability that the data is going up, the second if it is maintained, and the third one if it is going down.

PROMETHEE methods applied

Applying initial PROMETHEE II method, the authors obtain in $n+1$, the results shown in Table 11.

Results

The results obtained with this method are summarized in Figures 12 and 13.

In all the figures it can be seen that Cooperative is preferred, at present, and in the future.

Conclusions

The results obtained with the proposed methods seem to be the best alternative to give the water management in the Salta Province to a Cooperative. This role could be played by the actual 'Asociación de Consorcios de Usuarios de Aguas Públicas de Salta' (Consortium Association) with the competences delegated from the 'Agencia de Recursos Hídricos' (WR Agency). The fundamental hydrology infrastructure works in the authors' opinion should be paid by the Province

Government with funds coming from The Federal Investment Council. The canon due to water use would be transferred to the Cooperative. This entity would be responsible for hydrologic information network, water distribution, maintenance task, and police actions.

This election is robust, due to the fact that the authors have demonstrated that with the changes foreseen in a medium-range level, the alternative elected does not change.

Erosion Control by Crop Management

Introduction

This case study is located in the Chaco Area (Salta Province of Argentina). It has a low density of population in small cities located in important long mountain valleys, and Indian places named '*puestos*' or '*colonias*' (see Figures 14 and 15).

Figure 14 'Puesto' Wichi in J. V. González.

Figure 15 Typical housing in La Unión.

Figure 16 Provincial road in Chaco.

Figure 17 Bermejo River.

It has poor quality roads and it has an environment that is 'deteriorating progressively' (see Figure 16).

As said before, the Bermejo River (see Figure 17) is the most important fluvial artery in the area. It presents a zone known as a meander digression and due to low slopes its course changes constantly forming meanders. That area during monsoon rainy period is transformed into an immense sheet of floodwater that completely isolates the communities living by the river along 5–10 km from the riverside. It produces constant erosion that makes a great lot of sediments settling down at the Paraná River generating an important cost in the continuous drainage.

Figure 18 Pasture as *modus vivendi*.

One of the most important problems is the erosion, progressive desertification, and environment degradation. Besides the water, other factors have an important influence in the erosion and progressive desertification of this region and environment degradation. Historically, human exploitation of natural forest to be used in the railway and other activities produced an environment degradation process. Later on, the indigenous population followed the irrational wood extraction and did an over pasture as '*modus vivendi*' contributing to make the situation worse (see Figure 18). Actually, the farms and big single-crop exploitations in some locations do not give solution to the desertification problem.

For the study of this area, the authors have divided it into six zones: Las Lajitas, La Estrella, Pichanal, Martin Hickmann, Rivadavia banda sur, and Joaquín V. Gonzalez (see Figure 19).

Only one integral plan considering all factors involved and the differences among subzones, it will be an initial point to change the direction of the desertification process.

Alternatives of desertification control

The following five alternatives have been selected (see Table 12; Figures 20–24).

Criteria

Eight criteria have been applied following field research, expert panels, social investigation, and personal interviews. The criteria were rated on a 1–10 scale, according to local evaluations and other methods of elicitation.

Criterion 1: Water erosion

Water erosion (WE) is very important because of the interaction between natural and socioeconomic conditions. The relative WE indexes figure in the IM. For that the authors have considered this criterion as of the 'more is worst' kind.

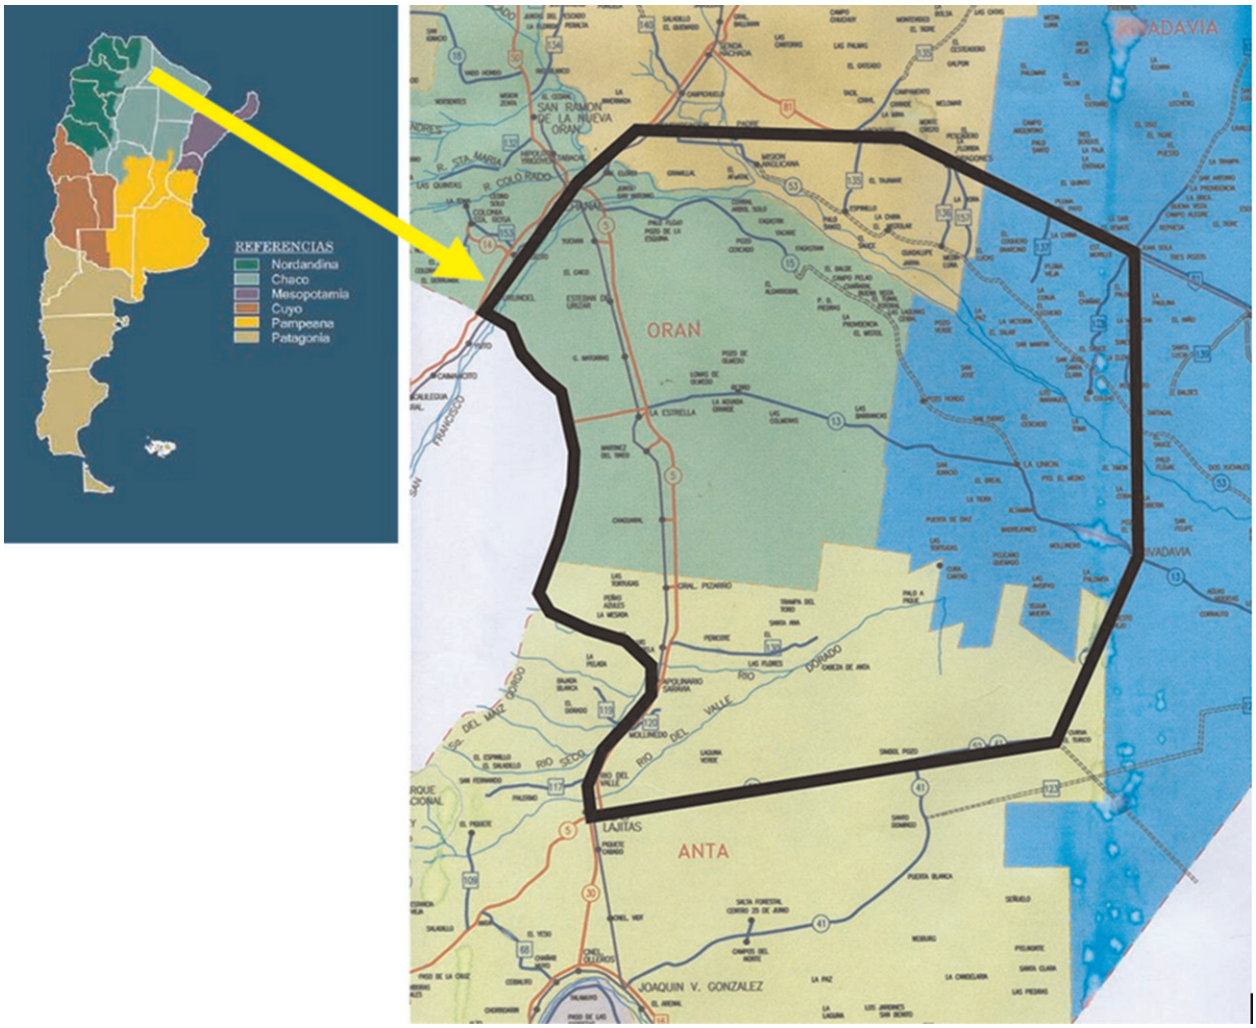

Figure 19 Study area.

Table 12 Five alternatives for 'Chaco'

No.	*Alternatives*	*Description*
1	Native forest	Trees like 'quebracho-blanco' and 'quebracho Colorado' (see **Figure 20**).
2	High value forest	Mainly teak, ebony, walnut tree, cherry tree, lignum vitae, eucalyptus, etc. (see **Figure 21**).
3	Traditional farms	Extensive agriculture and livestock mixed with native forest modified and several foraging plants (see **Figure 22**).
4	Erosion control crop with agriculture use	See **Figure 23**.
5	Erosion control crop with industrial use (biomass)	See **Figure 24**.

Criterion 2: Eolian erosion

Winds erosion, transport and deposit materials and are effective agents in several areas of this region. This criterion has been considered as of the 'more is worst' kind.

Criterion 3: Implementation facility

Have been established taking into account actors' opinions (Grau, 2003). This criterion is considered as 'more is better.'

Criterion 4: Water resources

By each alternative, the needs of WR have been considered. The relative results have been taken into the IM for this criterion. This criterion is considered as 'more is better.'

Criterion 5: Economical benefits

The relative economical benefits using each alternative in a period of 25 years have been obtained. This criterion is considered as 'more is better.'

Figure 20 Native forest in J. V. González.

Figure 21 High value forest in La Estrella.

Criterion 6: Hand power

The authors have considered that it would be satisfactory to give employment to the majority of the population. For that, they have considered this criterion as of the 'more is better' kind.

Criterion 7: Environmental impacts

They have been considered in each subzone. The environmental impacts (EI) have been calculated according to Gómez Orea (1999).

Criterion 8: Social acceptance

The figures included in this criterion have been obtained from the results of different forums and meetings with institutions, organizations, and native people (Grau, 2003).

Multicriteria methods applied

Initial matrix

In this article, the authors show the IM (see Table 13) and results using different discrete multicriteria decision methods for the subzone La Estrella. The recommendation for the total zone will be included in the conclusions.

ELECTRE method

From the IM using MATHCAD program the following graph and kernel (see Figure 25) are obtained.

Alternatives A and B are the preferred ones.

PROMETHEE method

From the IM using the pseudocriteria shown in Table 14 and weighted PROMETHEE II with Mathcad program, the results shown in Figure 26 are obtained.

The higher total flux is in relation to the preferred alternative. In this case, it is alternative B: High value forest.

Analytic hierarchy process method

From the IM (see Table 13) using Expert Choice Software, the following order (see Figure 27) is obtained:

Native forest, high value forest, traditional farms, erosion control crop with industrial use (biomass), and erosion control crop with agriculture use.

Conclusions

All the methods show consistency in the selection of the best alternative to control desertification in Chaco area (Salta Province of Argentina). The weighted PROMETHEE II method is a very useful tool to design an erosion control integral plan. It is robust as the authors have confirmed by changing, a little, the relative preferences. They recommend the use of weighted PROMETHEE II with the usual criterion and type III pseudocriterion.

Following the results obtained for the total zone, the authors recommend the following:

- Las Lajitas: Extensive farming and livestock. If it is only farming it could be with crop rotation. The livestock would be with natural forestry and foraging plants.
- La Estrella: Native and high value forestry can be combined.
- Pichanal: Similar to Las Lajitas.
- Martin Hickman: Native forestry.
- Rivadavia Banda Sur: Similar to La Estrella.
- Joaquin V. González: Similar to Las Lajitas combined, in some areas, with high value forestry.

Waste Management

Introduction

Worldwide, the management of urban solid waste (USW) of all types is a major problem and it is more virulent in areas that lack financial, technological, and cultural resources. It is difficult to convince the population to avoid casting waste into rivers or into open dumps. The domestic waste must not be disposed into the river or free air deposits. In general, this disposition affects not only the flora and small fauna destroying the biodiversity but also the health of people living in their margins. To avoid this situation, it is necessary to change the culture of the people. The means are limited, so it will be necessary to move resources from other public services.

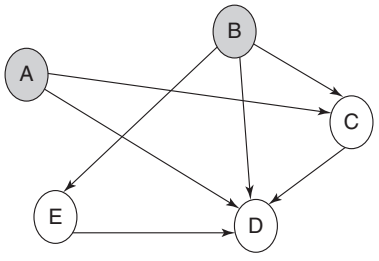

Figure 25 ELECTRE graph showing the kernel (subzone La Estrella).

This situation of USW currently involves the following consequences:

- The pollution of surface and groundwater that produces serious health problems and water-treatment costs, which are unaffordable in many cases by the municipal resources.

- Degradation of the soil by the presence of heavy metals and other pollutants. Soils are degraded, making them unproductive and potentially damaging to wildlife and citizens.
- Waste incineration produces air pollution.
- The gases produced by organic matter decomposition (carbon dioxide and methane) contribute to the greenhouse effect.
- The proliferation of disease vectors that directly or indirectly affects public health.
- The wind dispersal of many wastes, which also affects the environment and the countryside that are a propellent of wildland fire.
- A medium- and long-term factor of erosion, desertification, and climate change.

Abbreviations: EB, economical benefits; EE, Eolian erosion; EI, environmental impacts; HP, hand power; IF, Implementation facility; SA, social acceptance; WE, Water erosion; WR, water resources.

The problem was considered first by Prof. J.B. Grau during the time of his association with universities and public organizations of Salta in 2003 and 2004 (Grau, 2003). From these previous studies an MCDM problem of election between three alternatives considering a set of criteria was stated in adapted formats of ELECTRE-1, PROMETHEE, and AHP methods. Some indecision peculiarities were detected and needed critical reasoning to obtain some of the results. Actually a project is being developed in municipalities of Córdoba province (Argentina).

This case study was located in one area of the Salta Province (Argentina). The selected Andean area is very rich in natural resources and has a low density of population in small cities located in important long mountain valleys, has low standards for roads, and has an environment that according to

Table 15 Alternatives

No.	*Alternatives*	*Description*
1	Direct local sanitary filling	Disposal of residues in mass in such filling located in the source municipality.
2	Sanitary filling and compost Production	Disposal of inorganic residues in a direct local filling and compost production from organic residues in an adjacent plant.
3	Transport to external plants	The residues are carried to the nearest sanitary plant located out of the municipality.

Table 16 Criteria

No.	*Aspects*	*Criteria*	*Indexes (I_j)*	*Weights (W_j)*	
1	Technical aspects	(EIM)	Ease in management	−1	0.05
2	Environmental aspects	(LOC)	Location	+1	0.1
3		(LEI)	Local environmental impact	−1	0.15
4	Economic aspects	(ICO)	Installation costs[a]	−1	0.15
5		(OCV)	Operating costs net present value[a,b]	−1	0.15
6	Social aspects	(LDE)	Labor demand	+1	0.15
7		(CTP)	Compatibility with traditional practices	+1	0.05
8		(SAC)	Social acceptance	+1	0.15
9	Normative aspects	(CLR)	Compatibility with effective laws and rules	+1	0.05

[a]Costs are in thousands of pesos of Argentina (study in 2004), for a typical example municipality.
[b]Operating costs minus perceived incomes valued at start date as NPV; alternative 2 costs more initially but produces compost sales incomes that have been prudently estimated.
Note: Each criteria contains two data as (I_j; W_j); the I_j are indexes being 1 if the criterion is of the kind 'more is better' and −1 if it is of the kind 'more is worse'; the W_j are weights, having already 1 as sum in this example, as defined and used by ELECTRE and PROMETHEE methods later.

local opinion is 'deteriorating progressively.' White *et al.* (1995) and Chang *et al.* (1997) studied solid waste management, interesting for any human concentration; literature and pages for Latin America are easily found on the web, and Gallardo and Bordás (2001), Peñuelas *et al.* (2001) and Santos *et al.* (2001) are Spanish examples. The problem of urban residue management in that area was considered at this time by local officials and experts, and is contained in internal surveys considering the local aspects: territorial, socio-economic, and environmental. Discrete multicriteria decision methods were appropriated to reflect the criteria of different nature occurring in territorial studies, and three different

Figure 29 Concordance matrix C, discordance Matrix Dsc, average thresholds.

methods of disposal of these residues were adopted as alternatives.

Alternatives

The following three alternatives have been selected (see Table 15).

Criteria

These studies put in evidence for MCDAM nine criteria grouped into five aspects. These are shown in Table 16.

Multicriteria methods applied

ELECTRE-I method

Table 17 shows the initial decision matrix of data elements for the nine criteria and the three alternatives, as collected by J. Grau and D. Sánchez in Salta in 2004 for the rather transparent ELECTRE-I method. Some criteria were costs/benefits put in monetary values as said before, and other criteria received rather subjective indexes with values {1, 2 or 3} depending on the importance of the effect. As said an index I_j was assigned to each criterion, and a weight value W_j, already standardized, carefully chosen by the analysts.

From these data, following Roy (1985), the authors obtain the decisional matrix (D) standardized and weighted in Figure 28.

Figure 29 shows concordance and discordance matrixes, obtained with MATHCAD, and first values for thresholds *ucc* and *uds* that are the average of the six nondiagonal elements of matrixes C and Dsc. Finally, changing the thresholds and in spite of higher initial costs, alternative 2 may be considered preferable.

PROMETHEE methods

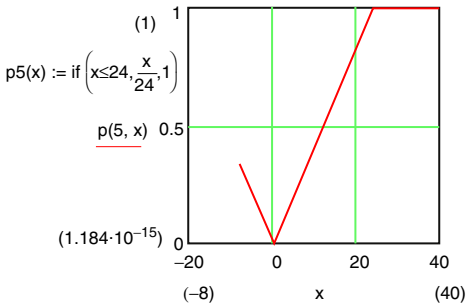
PROMETHEE methods were next considered following Brans and Mareschal conserving the precedent consensus election of criteria and tradeoffs by adopting the initial decision matrix, the indexes column I_j and the weights $w_j = \pi_j$ of Table 17, and by using 'type III, Criterion with Linear Preference Functions.' Figure 30 indicates one of the qualifying functions.

The results obtained with initial Brans PROMETHEE I and II are shown in Figure 31.

The results obtained with weighted PROMETHEE I and II are shown in Figures 32 and 33.

The higher Net flux is in relation to the preferred alternative. In this case, it is alternative 2: Sanitary Filling and Compost Production.

Analytic hierarchy process method



Using the AHP method, the second (sanitary filling + compost) alternative was preferred as before, followed by the first (direct filling) near the third (transport to external plants). The relative order of the first and the third has changed. The obtained performance sensitivity graph of Figure 34 contains some data and results, showing that environment impact had got a higher preference than for ELECTRE.

Pseudocriteria

- m = r–s
- j = 1 type III, s = 1, r = 2,
- j = 2 type III, s = 1, r = 2,
- j = 3 type III, s = 1, r = 3,
- j = 4 type III, s = 48, r = 75,
- j = 5 type III, s = 18, r = 42,
- j > 5 type III, s = 1, r = 3,

$$p(j, x) := \text{if}\left(x \le m_j, \frac{x}{m_j}, 1\right)$$

$p5(x) := \text{if}\left(x \le 24, \frac{x}{24}, 1\right)$

$p1(x) := \text{if}\left(x \le 1, \frac{x}{1}, 1\right)$ $p2(x) := \text{if}\left(x \le 1, \frac{x}{1}, 1\right)$ $p3(x) := \text{if}\left(x \le 2, \frac{x}{2}, 1\right)$

$p4(x) := \text{if}\left(x \le 27, \frac{x}{27}, 1\right)$

$p5(x) := \text{if}\left(x \le 24, \frac{x}{24}, 1\right)$

Figure 30 Qualifying function in PROMETHEE.

Initial PROMETHEE I and II

$$q(i, ii) := \frac{\sum_{j=1}^{9} P(i, ii, j)}{9}$$

$qq_{i,ii} := q(i,ii)$

$$qq = \begin{bmatrix} 0 & 0.214 & 0.222 \\ 0.389 & 0 & 0.444 \\ 0.342 & 0.389 & 0 \end{bmatrix}$$

Outgoing flux : $fp(i) := \sum_{ii=1}^{3} q(i, ii)$ $fpp_i := fp(i)$

$$fpp = \begin{bmatrix} 0.436 \\ 0.833 \\ 0.73 \end{bmatrix}$$

Incoming flux : $fm(i) := \sum_{ii=1}^{3} q(ii, i)$ $fmm_i := fm(i)$

$$fmm = \begin{bmatrix} 0.73 \\ 0.603 \\ 0.667 \end{bmatrix}$$

PROMETHEE I

$pr(i,ii) :=$ z←−1; z←0 if (fp(i)=fp(ii))·(fm(i)=fm(ii)); z←1 if ((fp(i)>fp(ii))·(fm(i) < fm(ii))) + ((fp(i) > fp(ii))·(fm(i)=fm(ii))) + ((fp(i)=fp(ii))·(fm(i) < fm(ii))); z

$$prr = \begin{bmatrix} 0 & -1 & -1 \\ 1 & 0 & 1 \\ 1 & -1 & 0 \end{bmatrix}$$

PROMETHEE II

Net flux: $fd(i) := fp(i) - fm(i)$ $fdd_i := fd(i)$

$$fdd = \begin{bmatrix} -0.294 \\ 0.23 \\ 0.064 \end{bmatrix}$$

With both methods: Order: 2,3,1

Figure 31 Results with initial PROMETHEE I and II.

Conclusions

In a global study the sanitary filling and compost alternative was preferred with the three methods. The direct filling and the transport out of the city alternatives were rather equivalent. For application in practice programming of actions would be required, actuations could be started progressively through independent initiatives by municipalities; a central agency could offer technical information and pilot plant experimentation,

$$P(i, ii, j) := \text{if}[l_j \cdot (t_{j,i} - t_{j,ii}) \le 0, 0, p(j, |t_{j,i} - t_{j,ii}|)]$$

$$qq = \begin{bmatrix} 0 & 0.189 & 0.25 \\ 0.425 & 0 & 0.5 \\ 0.311 & 0.325 & 0 \end{bmatrix} \qquad q(i, ii) := \frac{\sum_{j=1}^{9} P(i, ii, j) \cdot W_j}{9}$$

$i := 1...3 \quad ii := 1...3 \quad qq_{i,ii} := q(i, ii) \cdot 9$

Outgoing fluxes: $fp(i) := \sum_{ii=1}^{3} q(i, ii) \quad fpp_i := fp(i)$

$$fpp = \begin{bmatrix} 0.046 \\ 0.1028 \\ 0.0679 \end{bmatrix}$$

Incoming fluxes $fm(i) := \sum_{ii=1}^{3} q(ii, i) \quad fmm_i := fm(i)$

$$fmm = \begin{bmatrix} 0.0818 \\ 0.0515 \\ 0.0833 \end{bmatrix}$$

Figure 32 Result with weighted PROMETHEE I and II (part 1).

Weighted PROMETHEE I

$pr(i,ii) := |z \leftarrow -1$

$z \leftarrow 0 \text{ if } (fp(i)=fp(ii)) \cdot (fm(i)=fm(ii))$

$z \leftarrow 1 \text{ if } ((fp(i)>fp(ii)) \cdot (fm(i) < fm(ii))) + ((fp(i) > fp(ii)) \cdot (fm(i)=fm(ii))) + ((fp(i)=fp(ii)) \cdot (fm(i) < fm(ii)))$

$prr_{i,ii} := pr(i,ii)$

Where pr(i,ii) = 1 means that action i outranks action ii, pr(i,ii) =0 is equivalence, and pr(i,ii) = –1 indetermination maybe solved looking at pr(ii,i)

$$prr = \begin{bmatrix} 0 & -1 & -1 \\ 1 & 0 & 1 \\ -1 & -1 & 0 \end{bmatrix}$$

2 is better than 1 and 3 but 3 do not outrank to 1

Weighted PROMETHEE II

Net flux: $fd(i) := fp(i) - fm(i) \qquad fdd_i := fd(i)$

$$fdd = \begin{bmatrix} -0.0358 \\ 0.05123 \\ -0.01543 \end{bmatrix}$$

Order: 2,3,1

Alternative 2 is preferred

Figure 33 Result with weighted PROMETHEE I and II (part 2).

and investment subsidies. The selected MCDM methods have been suitable as aid for the planning of such practical and real problem. ELECTRE-I was clear as a first guide but required addenda of additive valuations for decision, AHP was more dependent on analysts that emphasized environmental aspects diminishing the influence of social aspects, and PROMETHEE was efficiently adapted by the use of linear preferences and weights as used with ELECTRE-I. This method is named weighted PROMETHEE and is actually used in many real cases.

Final General Model

With the experience obtained from the above four cases the authors have elaborated a model to apply to climate change.

In the first place, the following alternatives and criteria are adopted.

Alternatives

1. Industrial and agricultural activities reduction in first world: To prepare and to sign a Memorandum of Understanding (MoU), similar to Kyoto Protocol in order to reduce, step by step, the industrial and agricultural dangerous activities mainly in developed countries.
2. To maintain the activities in industrial countries transferring funds to improve environmental activities compatibles with sustainable progress in the third world: To prepare and to sign a protocol in order to establish a mechanism similar to 'green-bonus.'

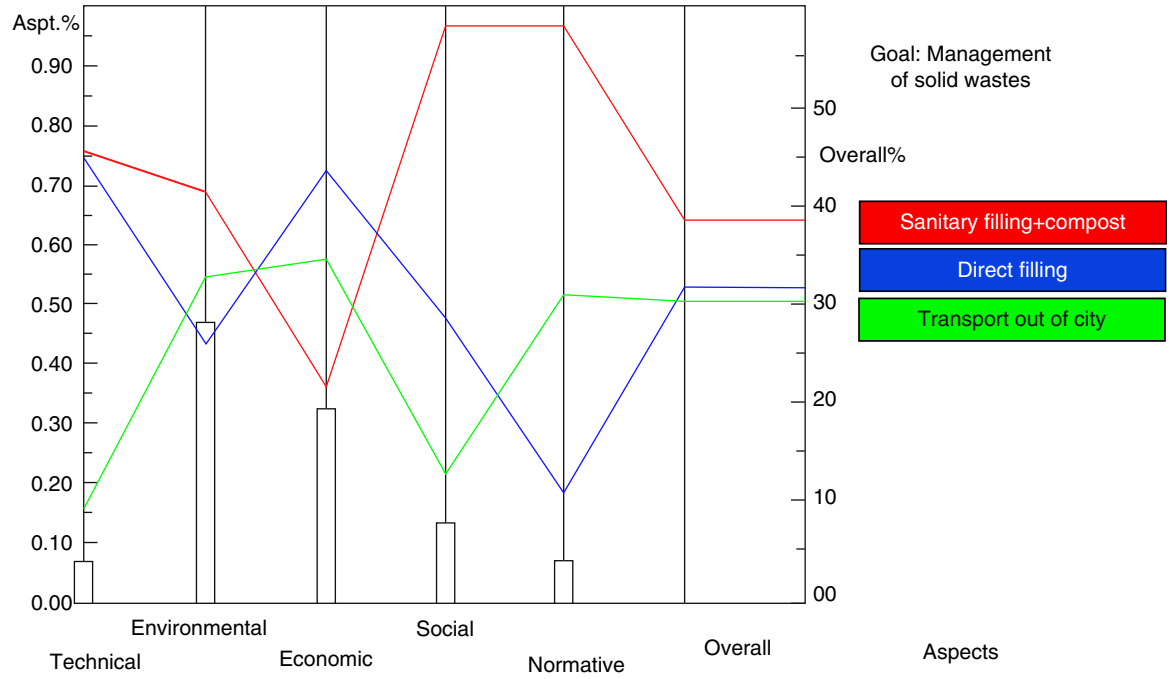


Figure 34 Results Analytic Hierarchy Process using Expert Choice software.

3. To Increase economic support to countries and activities aimed at improving the environment.
4. To give resources to research groups in order to study integral adaptation plans: To increase the subvention and funds from international entities like European Commission through the CALLS as CALL FP7 – ENV – 2012 "Strategies, costs and impacts of adaptation to climate change" in order to encourage the research groups to dedicate the efforts to this activity.
5. To help natural reactions: From the creation of the world the earth has been changing and the natural resources included the human people have been adapting to those changes. The human action would be to help the natural forces to adapt us to new situations.
6. To maintain actual policy: To follow with the studies, convention and action in the framework of International Organizations.

Criteria

Environmental criteria

- Peak runoff, of the kind 'more is worse.'
- Average annual erosion (ERO), of the kind 'more is worse.'
- Index of Environmental Quality (EQI), of the kind 'more is better.'

Economic criteria

- Investment (INV), of the kind 'more is worse.'
- Maintenance (MAN), of the kind 'more is worse.'
- Benefits (BEN), of the kind 'more is better.'

Social criteria

- Ease for implementation (FIM), of the kind 'more is worse.'
- Social acceptability (ACE), of the kind 'more is better.'
- Employment impact (EMP), considered of the kind 'more is better.'

Physical type

- Meteorological: Monthly pluviometry (mm) of rain in the last 50 years and maximum rain in 6 h month by month in the last 50 years. Overflows, earthquake, cyclone year by year during last 50 years. Some cases will be the kind 'more is better' and in others 'more is worse.'
- Soil (SOI): Classification following the method developed by Antón and Grau (2009). It is of the kind 'more is better.'
- Water resources (WR). It is of the kind 'more is better.'

The use of soil

In relation to the use of soil, several criteria must be considered:

- Agricultural use (AGR), livestock (LIV), forestry (FOR), mining (MIN), industrial (IND), urban (URB), and sport and tourism (TOU). Some cases will be of the kind 'more is better' and in others 'more is worse.'

Political Criteria

- Legislation in force (LEG), to be in accordance with it is positive for adopting the solutions in an alternative, and it was measured by a valuation (*qi.*) in the range (1–10) 'more is better' scale.
- Votes gained or lost (VOT).

Initial Matrix

With the preliminary studies and the database elaborates for the interdisciplinary research groups, the authors create the initial decisional matrix (see Table 18).

Multicriteria Methods Applied

The following discrete MCDM has been applied:

- ELECTRE – TRI, see Roy (1985, 1996), Roy and Bouyssou (1993), and Mousseau *et al.* (2000) and other versions.
- For initial PROMETHEE, see Brans and Vincke (1985), Brans *et al.* (1986); from it is derived the adopted weighted PROMETHEE that seems preferable to introduce indication of relative importance of criteria, see Brans and Mareschal (1994), Anton *et al.* (2006, 2010), and Grau *et al.* (2008, 2009).
- AHP, see Saaty (1980, 1996a,b).

For ELECTRE and PROMETHEE methods, MATHCAD® software was used, and for AHP method, EXPERT CHOICE® software (from EXPERT CHOICE Inc). These methods got successively varied extensions and also commercial software, but for the goals of this article the adopted versions were robust and reliable. These methods have been used by the authors formerly in other applications such as: 'Madrid-Valencia high-speed rail line: A route selection' (Anton *et al.*, 2004), 'Compromise Programming Calibration for financial analysis of firms of a common sector of business, case study for a set of Spanish banks in 1995' (Antón *et al.*, 2007), and 'Application of decision theory methods for a Community of Madrid soil classification' (Antón *et al.*, 2007).

Other Methods

Bayesian methods and statistical methods using time series will be used completing some aspects. These have been tested in the case study 4.2. For the DSS used here, the Bayesian views considering various states of future that may change, such as in climate or in human uses, as populations, products and markets, normally with elicited probabilities at decision time, and sometimes with elicited utility functions, and maybe with changes in opinion transferred perhaps into elicited weights. These points of views are also used with high initial spending, but that is not the case here unless great public works, as of hydraulic management, are indicated against climate change.

Advantages of the Proposed Solution

The advantages of the proposed solution are:

- The models that currently exist, analyzed individually the variables that are altered by climate change (water, CO_2, temperature, greenhouse gases, etc.) without considering it in an integrated way to understand how they can affect life on earth. However, this model allows us to see how the life on earth, including human people, can be affected by changes in all the variables analyzed. This can be

Table 18 Initial matrix

		Criteria

considered as a next step to the final report of MCA4 climate initiative (see UNEP, 2011).

- It is a global solution applicable in every geographical area.
- It takes full advantage of the existing information and it makes the maximum use of efforts carried out by research groups, universities, and different institutions.
- The proposed model generates results that can be more easily borne by society in accepting the mitigation and adaptation plans to climate change.
- It generates a scientific base that can be analyzed, adapted, and presented at international decision forums.
- Many of the current models to foresee certain changes can serve as a basis and support to the proposed integrated model.
- The model will quantify the costs of actions derived from the implementation of the proposed alternatives.

Medicinal Crops

L Zhou, J Xu, and Y Peng, China Agricultural University, Beijing, China

© 2014 Elsevier Inc. All rights reserved.

Glossary

Biosynthesis Enzyme-catalyzed process in cells of living organisms by which substrates are converted to more complex products.

Good agricultural practices Specific methods applied to agriculture create food for consumers or further processing that is safe and wholesome.

Medicinal plants Plants used as natural medicines.

Plant endophytic fungi Fungi that spend the whole or part of their lifecycle colonizing intracellularly inside the healthy tissues of host plants, typically causing no apparent symptoms of disease.

Traditional Chinese medicines Medicines sharing common concepts which have been developed in China and are based on a tradition with a long time.

Introduction

Medicinal crops are designated as cultivated/semicultivated plants for prevention/treatment of human/animal diseases. They include cultivated medicinal fungi such as Chinese caterpillar fungus (*Cordyceps sinenesis*), *Coriolus versicolor*, *Ganoderma lucidum*, *Polyporus mylittae*, *Polyporus umbellatus*, *Poria cocos*, and *Lentinus edodes* (Philippoussis *et al.*, 2007); cultivated lichens such as *Thamnolia vermicularis*, *Umbilicaria esculenta*, and *Usnea diffracta*; cultivated mosses such as *Conocephalum conicum*, *Marchantia polymorpha*, and *Sphagnum palustre*; cultivated ferns such as *Huperzia serrtata*, *Lycopodium japonicum*, *Cibotium barometz*, *Alsophila spinulosa*, and *Dryopteris crassirhizoma*; and a large number of cultivated seed plants (higher plants) including gymnosperms and angiosperms.

An increasing number of new drugs with efficacy against some common diseases have been derived from medicinal plants. These include artemisinin from *Artemisia annua* for the treatment of malaria, Folium Ginkgo (*Ginkgo biloba* leaves) extract EGb 761 for age-related memory disease (Alzheimer's disease), and *Salvia miltiorrhiza* extract for cardiovascular disease. However, the increasing use of medicinal plants for healthcare and the plant medicine boom in recent years have imposed a great threat to the conservation of natural resources and endangered plant species (Zhou and Wu, 2006). Owing to overexploitation, wild medicinal plants have become rare (e.g., *Aconitum deinorrhizum*, *Panax* spp., *Paris polyphylla* var. *yunnanensis*, *Rheum emodi*), threatened (e.g., *Berberis artistata* and *Rauvolfia serpentina*), and endangered (e.g., *Dioscorea deltoidea*, *Sassurea lappa*, *Taxus* spp.). This has caused serious ecological damage and rapid genetic loss of medicinal plants, which have forced the need for cooperation and coordination to undertake programs for conservation of medicinal plants to ensure that adequate quantities are available for future generations. Cultivation of medicinal plants can meet the long-term use of medicinal plant resources. Furthermore, it gives scope to improve the quality of the drugs. Many medicinal crops are also used for cosmetic and aromatic purposes, and thus the definition medicinal, aromatic, and cosmetic plants would better describe such crops (Lubbe and Verpoorte, 2011). The medicinal crops discussed in this article are limited to cultivated seed plants.

Resources and Distribution

Medicinal plants are mainly distributed in the tropical and subtropical areas of the world. Accordingly, medicinal crops are also widely cultivated in these areas. They mainly belong to the families Araliaceae, Boraginaceae, Compositae, Dioscoreaceae, Gentianaceae, Lamiaceae, Leguminosae, Liliaceae, Papaveraceae, Rutaceae, Solanaceae, and Umbelliferae. Most of them are herbal plants. **Table 1** shows the main medicinal plants cultivated throughout the world.

Processing and Utilization

Processing of medicinal crops means to dry and then cut or powder the whole plant or just one part of the plant (i.e., flowers, roots, stems, leaves, and seeds). They can be treated with solutions (e.g., water or organic solvents) to obtain crude extracts, which will be further separated to obtain pure bioactive substances. Both crude extracts and pure substances can be used as medicines.

The isolated bioactive components of medicinal crops can be developed either as pharmaceuticals directly or as starting materials for the pharmaceutical industry to produce semisynthetic pharmaceuticals (e.g., cortisone and progesterone; Houghton, 2001). Examples of the former include antimalarial artemisinin from *A. annua*, antimicrobial berberine from *Coptis sinensis*, anticancer alkaloid paclitaxel (taxol) from yew trees (*Taxus* spp.), Sanchi saponins from *Panax notoginseng*, vinblasine from the Madagascar periwinkle (*Catharanthus roseus*), and digoxin from foxglove (*Digitalis lanata*). A good example of the latter is the use of plant steroids (e.g., diosgenin), such as those extracted from yams (*Dioscorea* spp.), to semisynthetically produce corticosteroids and oral contraceptives. Plant-derived components play an important role in the production of such 'single chemical entity' medicines. More than 25% of the pharmaceutical drugs used in the world today are derived from plant natural products (Farnsworth, 1979; Schmidt *et al.*, 2008). **Table 2** lists some examples of plant-derived drugs.

Medicines in the form of extracts, teas, tinctures, or capsules produced from medicinal plants are referred to as

Table 1 Examples of the main medicinal crops distributed throughout the world

Medicinal plant (family)	*Region (country)*
Acacia farnesiana (L.) Willd. (Leguminosae)	Africa
Adenanthera pavonina L. (Leguminosae)	Africa and South Asia
Aegle marmelos (L.) Correa. (Rutaceae)	South Asia (Malaysia and Thailand)
Aesculus hippocastanum L. (Sapindaceae)	Europe (Greece)
Aloe barbadensis Mill. (Liliaceae)	North Africa and South America
Alstonia boonei Wild. (Apocynaceae)	Africa
Alstonia constricta (Apocynaceae)	Australia
Ammi majus L. (Umbelliferae)	South Asia
Andrographis paniculata Nees. (Acanthaceae)	South Asia
Angelica sinensis (Oliv.) Diels (Umbelliferae)	Asia (China)
Annona squamosa L. (Annonaceae)	Australia, Asia (China), and Central America
Aquilaria agallocha (Lour.) Roxb.	Australia and Southeast Asia (China, Indonesia, Malaysia, and Vietnam)
Arctostaphylos uva-ursi (L.) Spreng. (Ericaceae)	Europe
Artemisia absinthium L. (Compositae)	Asia, Europe, and North America
Artemisia annua L. (Compositae)	East Asia (China)
Artemisia capillaries Thunb. (Compositae)	Asia (China)
Asclepias tuberosa L. (Asclepiadaceae)	North America
Astragalus membranaceus (Fisch.) Bunge (Leguminosae)	Asia (China)
Astragalus mongholicus Bunge (Leguminosae)	Asia (China)
Atractylodes macrocephala Koidz. (Compositae)	Asia (China)
Azadirachta indica A. Juss.(Meliaceae)	Asia (Burma, and India)
Cananga odorata (Lamk.) Hook. f. et Thoms. (Annonaceae)	South Asia and Africa
Carthamus tinctorius L. (Compositae)	Asia (China)
Centella asiatica (L.) Urban (Umbelliferae)	Africa, Asia, and Australia
Chondrodendron tomentosum (Menispermaceae)	Central America and South America
Cinchona ledgeriana (Howard) Moens et Trim (Rubiaceae)	South America and Africa
Cissus modecoides Planch. var. *subintegra* Gagn (Vitaceae)	Central America
Codonopsis pilosula (Franch.) Nannf. (Campanulaceae)	Asia (China)
Cola acuminata Schott et Endl. (Sterculiaceae)	South America (Brazil) and West Africa (Nigeria)
Coleus forskohlii (Willd.) Briq. (Lamiaceae)	Southeast Asia (Bhutan, China, India, and Nepal)
Coptis chinensis Franch. (Ranunculaceae)	Asia (China)
Curcuma longa L. (Zingiberaceae)	South Asia (India)
Datura stramonium L. (Solanaceae)	South Asia (Iran) and South America (Ecuador)
Digitalis purpurea L. (Scrophulariaceae)	Europe
Dioscorea opposita Thunb. (Dioscoreaceae)	Asia (China)
Dioscorea zingiberensis C. H. Wright (Dioscoreaceae)	Asia (China)
Dolomiaea souliei Shih (Compositae)	Asia (China)
Dracaena draco L. (Liliaceae)	South America (Brazil)
Echinacea purpurea Moench (Compositae)	Europe
Ephedra sinica Stapf. (Ephedraceae)	Asia (China)
Eschscholzia californica Cham. (Papaveraceae)	North America
Eucalyptus globulus Labill. (Myrtaceae)	Australia and Asia (China)
Eucommia ulmoidea Oliv. (Eucommiaceae)	Asia (China)
Fallopia multiflora (Thunb.) Harald. (Polygonaceae)	East Asia (China)
Fritillaria cirrhosa D. Don (Liliaceae)	East Asia (China)
Gastrodia elata Blume (Orchidaceae)	East Asia (China)
Gentiana scabra Bunge (Gentianaceae)	East Asia (China)
Ginkgo biloba L. (Ginkgonaceae)	East Asia (China)
Glycyrrhiza uralensis Fisch. (Leuguminosae)	East Asia (China)
Hamamelis virginiana (Hamamelidaceae)	North America
Hydrastis canadensis (Ranunculaceae)	North America (Canada and USA)
Hyoscyamus niger L. (Solanaceae)	South Asia
Hypericum perforatum L. (Guttiferae)	North America, Europe, and Asia
Hyssopus officinalis (Lamiaceae)	Europe and Asia (India and Iran)
Lavandula angustifolia L. (Lamiaceae)	Europe
Levisticum officinale Koch. (Umbelliferae)	Asia, Europe, and North America
Lonicera japonica Thunb. (Caprifoliaceae)	Asia (China and Japan)
Lycium chinense Miller (Solanaceae)	East Asia (China)
Magnolia officinalis Rehd. et Wils. (Magnoliaceae)	East Asia (China)
Marsdenia condurango Reich. (Asclepiadaceae)	South America
Melaleuca alternifolia (Myrtaceae)	Australia

(*Continued*)

Table 1 Continued

Medicinal plant (family)	*Region (country)*
Mosla chinensis Maxim. (Poaceae)	South Asia
Myristica fragrans Houtt. (Myristicaceae)	South Asia (Indonesia and Malaysia)
Myroxylon pereirae L. (Leguminosae)	South America
Nigella damascene L. (Ranunculaceae)	North America
Ocimum sanctum L. (Lamiaceae)	Asia (China, India, Malaysia, Indonesia, and Philippines) and Australia
Oenothera erythrosepala Borb. (Onagraceae)	Europe, North America, South America, and Asia (China)
Olea europaea L. (Oleaceae)	North Africa
Panax ginseng C. A. Mey. (Araliaceae)	East Asia (China, Japan, and Korea)
Panax notoginseng F. H. Chen (Araliaceae)	East Asia (China)
Panax quinquefolium L. (Araliaceae)	North America (Canada and USA)
Papaver somniferum L. (Papaveraceae)	South Asia (India and Turkey) and South America (Ecuador)
Peganum harmala L. (Zygophyllaceae)	South Asia
Phellodendron amurense Rupr. (Rutaceae)	Asia (China)
Phellodendron chinense Schneid. (Rutaceae)	Asia (China)
Physostigma venenosum Balf. (Leguminosae)	West Africa
Phytolacca Americana L. (Phytolaccaceae)	North America
Pinellia ternate (Thunb.) Breit. (Araceae)	Asia (China)
Piper longum L. (Piperaceae)	South Asia
Piper methysticum Forst. (Piperaceae)	Europe
Piper nigrum L. (Piperaceae)	South Asia
Platycodon grandiflorus (Jacq.) A. DC. (Campanulaceae)	Asia (China, Japan, and Korea)
Podophyllum hexandrum (Berberidaceae)	Asia (India)
Polygala tenuifolia Wild. (Polygalaceae)	Asia (China)
Pueraria lobata (Willd.) Ohwi. (Pedaliaceae)	South Africa
Quassia amara L. (Simaroubaceae)	South America
Ranunculus ternatus Thunb. (Ranunculaceae)	South America and Asia (China)
Rauvolfia womitoria Afzel. (Apocynaceae)	South America
Rehmannia glutinosa Libosch. (Scrophulariaceae)	Asia (China)
Rhodomyrtus tomentosa Hassk. (Myrtaceae)	South Asia (India)
Ricinus communis (*Euphorbiaceae*)	East Africa
Rosmarinus officinalis L. (Lamiaceae)	Europe, North America (USA), and South America (Ecuador)
Saussurea costa Lipsch. (Compositae)	Asia (China)
Schisandra chinensis (Tuecz.) Baill. (Magnoliaceae)	Asia (China)
Scutellaria baicalensis Georgi (Lamiaceae)	Asia (China, Japan, North Korea, and Mongolia)
Solanum nigrum L. (Solanaceae)	Africa, Asia, Europe, and America
Strychnos nuxvomica (Loganiaceae)	Africa and South Asia
Swertia chirayita (Roxb. ex Flemi) Karsten (Gentianaceae)	South Asia (India)
Syzygium jambos (L.) Alston. (Myrtaceae)	Australia and South Asia
Tabernaemontana orientalis (Apocynaceae)	Australia
Thymus mongolicus Ronn. (Lamiaceae)	South America (Ecuador)
Vaccinium myrtillus L. (Ericaceae)	Europe (Germany)
Valeriana officinalis L. (Valerianaceae)	Europe
Vanilla fragrans (Salisb.) Ames. (Orchidaceae)	Australia, Asia, and Africa
Vanilla planifolia Jacks. ex Andrews (Orchidaceae)	West Africa
Viburnum opulus L. (Adoxaceae)	North America and Europe
Withania kansuensis Kuang et A. M. Lu (Solanaceae)	South Africa, South Asia (India), and Mediterranean
Zanthoxylum americanum P. Mill. (Rutaceae)	North America
Zingiber officinale Rosc. (Zingiberaceae)	Southeast Asia (China and India) and Europe

phytopharmaceuticals, phytomedicines, herbal medicines, and botanical drugs. Medicines are produced to high standards and must undergo clinical evaluation of safety and efficacy (Schmidt *et al.*, 2008). Clinical trials have been performed for many phytomedicines and for the most part it is known which constituents are responsible for the medicinal effect (Houghton, 2001). Phytomedicines are standardized in terms of active constituents. Examples of popular phytomedicines are *G. biloba* extract to improve cognitive function (O'Hara *et al.*, 1998), ginseng (*Panax ginseng*) as a general tonic and cognitive enhancer (Attele *et al.*, 1999), ginger (*Zingiber officinale* Rosc.) against nausea and vomiting (Ernst and Pittler, 2000), and Saw palmetto (*Serenoa repens*) for the treatment of symptomatic benign prostatic hyperplasia (Boyle *et al.*, 2004). Further examples of popular phytomedicines are shown in **Table 3**.

Partial Medicinal Crops

The following are descriptions of some selected important medicinal crops including their taxonomy, distribution, pharmacology, and bioactive components.

Table 2 Examples of commonly used pharmaceutical components of plants

Component	*Chemical class*	*Medicinal plant*	*Therapeutic use*
Artemisinin	Sesquiterpene	*Artemisia annua*	Antimalarial
Atropine	Tropane alkaloid	*Atropa belladonna*, *Hyoscyamus* spp.	Antispasmodic and pupil dilator
Berberine	Isoquinoline alkaloid	*Coptis sinensis*	Antimicrobials
Camptothecin	Indole alkaloid	*Camptotheca acuminate*	Antineoplastic
Digoxin	Steroidal glycoside	*Digitalis lanata*	Heart disorders
Galanthamine	Isoquinoline alkaloid	Various members of *Amaryllidaceae*	Against mild Alzheimer's disease and dementia
Gastrodin	Phenolic glycoside	*Gastrodia elata*	Have a good sedative and hypnotic effect
Morphine and codeine	Alkaloid	*Papaver somniferum*	Analgesic and antitussive
Paclitaxel	Diterpene alkaloid	*Taxus* spp.	Anticancer (ovarian)
Podophyllotoxin	Lignan	*Podophyllum* spp.	Antiviral and antineoplastic
Tanshinones	Diterpenoid quinone	*Salvia miltiorrhiza*	Cardiovascular diseases
Quinine	Quinoline alkaloid	*Cinchona* spp.	Antimalarial
Sanchi total saponin	Triterpenoid glycoside	*Panax notoginseng*	Inhibiting platelet aggregation and increasing cerebral blood flow
Scopolamine	Tropane alkaloid	*A. belladonna*, *Hyoscyamus* spp.	Sedative, against mortion sickness
Sanchi saponin	Triterpenoid	*P. notoginseng*	Promoting blood circulation by removing blood stasis
Vinblastine and vincristine	Indole alkaloid	*Catharanthus roseus*	Anticancer (leukemia)

Table 3 Examples of commonly used phytomedicines

Medicinal plant	*Active component*	*Source*	*Therapeutic use*
Angelica	Coumarins, ferulic acid, and volatile oil	*Angelica sinensis*	Invigorating blood, relieving pain, and moistening the intestines
Milkvetch	Triterpene glycosides and polysaccharide	*Astragalus* spp.	Immune modulator and antimicrobial
Black cohosh	Triterpene glycosides	*Cimicifuga racemosa*	Premenstrual symptoms and dysmenorrhea
Echinacea	Alkylamides	*Echinacea purpurea*	Immune modulator
Ephedra	Alkaloid	*Ephedra sinica*	Congestion, stimulant, and appetite suppressant
Feverfew	Sesquiterpene lactones	*Tanacetum pathenium*	Migraines and inflammation
Garlic	Allicin	*Allium sativum*	High cholesterol, hypertension, and respiratory infections
Ginkgo	Ginkgolides and flavonol glycosides	*Ginkgo biloba*	Mental fatigue and cognitive decline
Ginseng	Ginsenosides and eleutherosides	*Panax ginseng*	Fatigue and stress
Kava kava	Kavalactones	*Piper methysticum*	Anxiolytic
Purple gromwell	Shikonin and its derivatives	*Lithospermum erythrorhizon*	Antimicrobial and antiinflammatory
Saw palmetto	Phytosterols and fatty acids	*Serenoa repens*	Benign prostatic hyperplasia
St. John's wort	Hyperforins	*Hypericum perforatum*	Mild depression
Valerian	Iridoid glycosides, terpenoids, valerianic, and isovaleric acid	*Valeriana officinalis*	Anxiolytic, sleep improvement

Angelica (*Angelica sinensis*)

Angelica sinensis (Oliv.) Diels (family Umbelliferae) is a fragrant and perennial herb native to China, Japan, and Korea. It has been widely cultivated in the southwest of China. Chinese herbalists have used the roots of *A. sinensis* for thousands of years to strengthen heart, lung, and liver meridians, as well as lubricate the bowel. It has been considered as a blood tonic, and has been used by generations of women for health concerns such as menstrual pain and regulating the menstrual cycle. The roots of *A. sinensis* contain 0.4–0.7% volatile oil, the key components of which are *n*-butylidenephthalide, LIG (3-butylidene-4,5-dihydrophthalide), *n*-butyl-phthalide, ferulic acid (4-hydroxy-3-methoxycinnamic acid), nicotinic acid, and succinic acid. The extracts of *A. sinensis* and its active components have wide-ranging pharmacological activities on cardio- and cerebrovascular systems, antiinflammatory effect, immune support and hematopoiesis, and so on. Clinically, *A. sinensis* is officially listed in the Chinese Pharmacopoeia. It is one of the most commonly used traditional Chinese medicines, and has been used in the treatment of menstrual disorders, menorrhagia, and rheumatalgia. It is also used in many tonic preparations and Chinese patent drugs. Angelica root is used to replenish blood, invigorate blood, stop pain, and moisten the intestines. In the USA, *A. sinensis* is used for relief of vasomotor symptoms associated with menopause, including hot flashes, skin flushing, perspiration, and chills (Fang *et al.*, 2012).

Sweet Wormwood (*Artemisia annua*)

Artemisia annua L. (family Compositae) is an annual herb native to China. It grows in many countries such as Australia, Argentina, Bulgaria, France, Hungary, Italy, Spain, and the USA. *Artemisia annua* is used for the crafting of aromatic wreaths, as a source of essential oils used in flavoring of vermouth, and also as a source of artemisinin, a potent antimalarial drug. This herb has been used for malaria therapy in China for over 1000 years (Dhingra *et al.*, 1999). Artemisinin has a peroxide bridge to which its antimalarial properties are attributed. It has a unique structure and lacks a nitrogen-containing heterocyclic ring, which is found in most antimalarial compounds. The isolation and characterization of artemisinin from *A. annua* is considered one of the most novel discoveries in recent medicinal plant research. Artemisinin was isolated from the plant *A. annua* in 1972, and its structure was determined by X-ray analysis in 1979 (Krishna *et al.*, 2008; Balint, 2001).

Periwinkle (*Catharanthus roseus*)

Cathranthus roseus (L.) G. Don (family Apocynaceae) has a pantropic distribution, naturalized in continental Africa, America, Asia, Australia, southern Europe, and on some islands of the Pacific Ocean. This medicinal plant is cultivated as an ornamental, used particularly for beddings, borders, and for mass effect. It blooms throughout the year and is propagated by seeds or cuttings. *Cathranthus roseus* has been studied extensively for its remarkable anticancer constituents of terpenoid-indole alkaloid class such as vincristine and vinblastine. Among other components, ajmalicine and serpentine are used in relieving hypertension and related cardiac disorders (Mujib *et al.*, 2012).

China Goldthread (*Coptis chinensis*)

Coptis chinensis Franch. (family Ranunculaceae) has been used for more than 2000 years in China for treatment of damp-heat syndromes. The major active component in *C. chinensis* is berberine, an isoquinoline alkaloid. There are a few species in genus *Coptis* such as *C. chinensis*, *C. deltoidea*, *C. teetoide* in China, *C. japonica* in Japan, and *C. trifolia* in North America. In China, *C. chinensis* has been extensively cultivated in eastern Sichuan Province and western Hubei Province under good agricultural practice (GAP) for Chinese Crude Drugs. Berberine constitutes the most abundant alkaloid in the dried herb *C. chinensis*. This medicinal plant has long been recognized in the treatment of intestinal infections including acute gastroenteritis, cholera, and bacillary dysentery, which can be linked to their antibacterial, antiviral, and antiinflammatory effects (Kyoko *et al.*, 2007; Tang *et al.*, 2009).

Peltate Yam (*Dioscorea zingiberensis*)

The rhizomes of several species of the genus *Dioscorea* (family Dioscoreaceae), known as yam, are a food staple for the populations of Asia, Africa, and tropical America. Most species contain steroid saponins and sapogenins, such as diosgenin, which is the starting material of industrial interest in the synthesis of many steroids that are on the market as anti-inflammatory, androgenic, estrogenic, and contraceptive drugs. Furthermore, these steroids are reported to possess cytotoxic, antitumor, antifungal, immunoregulatory, hypoglycemic, and cardiovascular properties (Sautour *et al.*, 2007). *Dioscorea zingiberensis* C. H. Wright is the dominant source for diosgenin production in China. The rhizomes have a high content of diosgenin, which is approximately 8% on dry basis (Li and Ni, 2011).

Gastrodia (*Gastrodia elata*)

Gastrodia elata Blume (family Orchidaceae) is well known as an important substance for Chinese medicine in Asian countries. It is broadly distributed in the temperate and boreal regions of China, Korea, and Japan. Cultivation of *G. elata* is associated with the infection of the fungus *Armillaria mellea* (Cha and Igarashi, 1995). *Gastrodia Elata* is used to treat headaches, dizziness, tetanus, epilepsy, infantile convulsions, and numbness of the limbs, providing evidence that *G. elata* has central nervous system-protecting effects. Gastrodin and vanillin derived from *G. elata* show sedative and anticonvulsive effects. The crude extract had an anticonvulsive effect on kainite-induced seizures and epilepsy in rats, and an inhibitory effect on glutamate-induced cell death in IMR-32 human neuroblastoma cells, supporting the central nervous system actions of *G. elata* (Tsai *et al.*, 2011).

Ural Licorice (*Glycyrrhiza uralensis*)

Glycyrrhiza uralensis Fisch. (family Leguminosae) is an important perennial medicinal herb and is mainly cultivated in arid and semiarid areas in China. It has a long history of medicinal use in Europe and Asia to treat peptic ulcer disease, constipation, and cough. There are a variety of components in *G. uralensis* such as flavonoids, triterpenoids, stilbenoids, coumarins, and polysaccharides that show antiinflammatory (e.g., β-glycyhrritinic acid), antimicrobial (e.g., flavonoids), antiviral (e.g., glycyrrhizic acid), antiprotozoal (e.g., lichochalcone A), antioxidative (e.g., licochalcones A, B, C, and D), hepatoprotective (e.g., glycyrrhetinic acid), and antitumor (e.g., glycyrrhetinic acid) activities (Asl and Hosseinzadeh, 2008).

Purple Gromwell (*Lithospermum erythrorhizon*)

Lithospermum erythrorhizon Sieb. et Zucc. (family Boraginaceae) has been used traditionally as medicine in China, and as a dye for staining fabrics and food colorants. It has been cultivated in China, Korea, and other Asian countries. Shikonin and its naphthoquinone derivatives have been proved to be the active components that possess a wide spectrum of wound-healing, antitumor, antifungal, antiHIV, antioxidant, and contraceptive activities (Han *et al.*, 2008). The successful production of shikonin derivatives on a large scale from the cell, tissue, and hairy root (transgenic root) cultures of *L. erythrorhizon* has been achieved (Papageorgiou *et al.*, 1999; Syklowska-Baranek *et al.*, 2012).

Table 4 Examples of the medicinal compounds produced by both endophytic fungi and their host plants

Medicinal compound	*Endophytic fungus*	*Host plant*	*References*
Camptothecin	*Fusarium solani* INFU/Ca/KF/3	*Camptotheca acuminata*	Kusari *et al.* (2009)
Diosgenin	*Paecilomyces* sp. 80	*Paris polyphylla* var. *yunnanensis*	Cao *et al.* (2007)
Huperzine A	*Shiraia* sp. Slf14	*Huperzia serrata*	Zhu *et al.* (2010)
Hypericin	*Chaetomium globosum*	*Hypericum perforatum*	Kusari *et al.* (2008)
α-Irone and β-irone	*Rhizopus oryzae* 94Y-01	*Iris germanica*	Zhang *et al.* (1999)
Paclitaxel (Taxol)	*Alternaria* sp. Ja-69	*Taxus cuspidata*	Strobel *et al.* (1996)
Podophyllotoxin	*Phialocephala fortinii* PPE5	*Podopyllum peltatum*	Eyberger *et al.* (2006)
Vinblastine	*Alternaria* sp. 97CG1	*Catharanthus roseus*	Guo *et al.* (1998)
Vincristine	*Fusarium oxysporium* 97CG3	*C. roseus*	Zhang *et al.* (2000)

Boxthorn (*Lycium chinense*)

Lycium chinense Miller (Solanaceae) is mainly distributed in northern China. It is now widely cultivated in temperate and subtropical countries such as Japan, Korea, and other southeast Asian and European countries. The fruits have been used as a tonic in traditional Chinese medicine, and have been reported to exhibit hypotensive, hypoglycemic and antipyretic activities and to prevent stress-induced ulceration in experimental animals. Scientists have concentrated their attention on elucidating the bioactive components in *L. chinense*, which include polysaccharides, alkaloids, glycopeptides, glycoprotein, peptides, tocopherols, and flavonoids. Other species in the genus *Lycium* include *L. barbarum*, *L. yunnanensis*, and *L. ruthenicum*, which have similar medicinal functions (Qian *et al.*, 2004).

Panax spp. (*Panax ginseng*, *Panax notoginseng*, *Panax quinquefolium*)

Asian ginseng (*P. ginseng* C. A. Mey.), sanchi ginseng (*P. notoginseng* F. H. Chen), and American ginseng (*Panax quinquefolium* L.) are three important cultivated medicinal species in the family Araliaceae. *Panax ginseng*, which is cultivated in northeast China, Japan, and Korea, has been used for over 2000 years as a tonic, stimulant, and fatigue-resistance medicine. *Panax notoginseng*, which is distributed in southwest China (i.e., Yunnan and Guangxi), has been used for more than 400 years in the treatment of trauma and bleeding due to internal and external injury (Guo *et al.*, 2010). *Panax quinquefolium* is native to the hardwood-forest regions of the Eastern part of North America, but it has been successfully cultivated in New Zealand, China, Australia, Holland, France, and Poland (Kolodziej *et al.*, 2006). The main bioactive components in *Panax* species have been proved to be triterpenoid saponins, flavonoids, polysaccharides, and acetylenic compounds.

Yunnan Manyleaf Paris (*Paris polyphylla* var. *yunnanensis*)

Paris polyphylla var. *yunnanensis* (Franch.) Hand.-Mazz. (family Trilliaceae) is a perennial plant native to Yunnan Province, in the southwest of China. Its rhizomes have been used in traditional Chinese medicine as hemostasis, antimicrobial, and antiinflammatory agents for hundreds of years (Zhou *et al.*, 2003a). Its principal bioactive components are thought to be steroids, oligosaccharides, and polysaccharides (Zhou *et al.*, 2003b; He *et al.*, 2006).

Danshen (*Salvia miltiorrhiza*)

Salvia miltiorrhiza Bunge (family Lamiaceae) is a perennial herb widely used in Chinese traditional medicine for treatment of diseases such as coronary heart disease, cerebrovascular disease, hepatitis, hepatocirrhosis, chronic renal failure, dysmenorrhea, and neuroasthenic insomnia (Lu and Foo, 2002). Biologically active components in *S. miltiorrhiza* are considered as phenolic compounds (e.g., rosmarinic acid), tanshinones (e.g., cryptotanshinone), and polysaccharides. The polysaccharide SMP-W1 from the roots of *S. miltiorrhiza* displayed efficient immunoregulatory and antitumor activities (Liu *et al.*, 2013). Other species in the genus *Salvia* include *S. przewalskii* Maxim and *S. verticillata* L., which have similar medicinal functions (Matkowski *et al.*, 2008).

Medicinal Plant-Derived Bioactive Compounds Produced by Endophytic Fungi

Plant endophytic fungi are defined as fungi that spend the whole or part of their lifecycle colonizing inter- or intracellularly inside the healthy tissues of host plants, typically causing no apparent symptoms of disease. They are important components of plant microecosystems (Rodriguez *et al.*, 2009). Plant endophytic fungi are rich and potential resources for producing bioactive compounds with their potential applications in the agriculture, medicine, and food industries (Strobel, 2003; Zhou *et al.*, 2010; Kharwar *et al.*, 2011). Many valuable bioactive compounds with antimicrobial, insecticidal, cytotoxic, and anticancer activities have been successfully discovered from endophytic fungi. During the long period of coevolution, a friendly relationship is formed between each endophyte and its host plant. Some endophytes have the ability to produce the same or similar bioactive compounds as those originated from their host plants (Zhao *et al.*, 2011). Table 4 lists some examples of the medicinal compounds produced by both endophytic fungi and their host plants. Bioactive compounds of the partial medicinal plants could be produced by endophytic fungi through fermentation on a large scale. This could be an important approach for plant resources protection as well as for ecological and environmental conservation.

Conclusions and Future Perspectives

Many wild medicinal plants have become rare, threatened, or endangered due to overexploitation (Chatterjee, 2002). To conserve wild medicinal plant resources and to use them sustainably, the intensive cultivation of medicinal plants is crucial. Countries such as China, India, Indonesia, and Brazil are famous for cultivation and utilization of medicinal crops. GAP for the production of medicinal crops has made great progress through planning and drafting, examination, promulgation, and enforcement since 1999 in China (Ding *et al.*, 2012). Furthermore, bioactive components of medicinal plants could be produced by means of biotechnology (Zhou and Wu, 2006). Biosynthesis of some medicinal compounds may be stimulated by the endophytes existing in medicinal plants, and some medicinal compounds may be produced by the endophytes (Zhao *et al.*, 2011). Thus, the coevolutions on medicinal component biosynthesis between medicinal plants and their endophytes should be studied in detail.

Glossary

Oomycota A fungal-like chromistan that produces oospores; a water mold related to algae.
Pathogenesis-related proteins Groups of proteins with different chemical properties produced in a cell within minutes or hours following inoculation but all being more or less toxic to pathogens.
Phytoalexin A substance that inhibits the development of a fungus on hypersensitive tissue formed when host plant cells come in contact with the parasite.
Rhizosphere The soil near a living root.
Systemic acquired resistance Systemically activated resistance after primary infection with a necrotizing pathogen accompanied by increased levels of salicylic acid and pathogenesis-related proteins.

Introduction

One of the fundamental strategies for maintaining plant health is to manage the nutritional status of the plant (Datnoff *et al.*, 2007a). Nutrition can often govern the fine line between a crop's susceptibility and resistance to a plant disease. Complete and balanced nutrition should always be the first line of defense against the development of a plant disease. One major problem in providing proper nutrition is that many agronomic and horticultural crops vary in their nutritional requirements and those different nutrients may affect different diseases in different ways. Furthermore, the fertilization regimes necessary to maximize plant health when a plant pathogen is present can differ from optimal fertilization when the pathogen pressure is absent. This article provides an overview of the governing role of nutrition on crop health as related to resistance and susceptibility to disease.

In many cases, the amount of a nutrient needed to suppress a plant disease may far exceed a healthy plant's nutritional requirement for that nutrient, suggesting that many nutrients may participate in multiple mechanisms for plant disease suppression. Chemical interactions with the rooting medium, pH, and specific communities of microorganisms can, in turn, influence disease development. For example, the form of nitrogen (N) can have striking effects on plant disease through root-mediated changes in pH, microbial profile in the root zone, and alterations in the availability and function of micronutrients. Moreover, calcium (Ca) composes only approximately 0.5% of the dry weight of most plants, yet Ca is routinely applied in great quantities to container mixes to affect root medium pH and suppress certain plant diseases. These observations suggest that these inorganic elements are influencing disease directly through physiological mechanisms and indirectly through soil interactions that, in turn, affect the activity of plant pathogens.

Both essential and beneficial elements can affect disease defense mechanisms in plants. These nutrients play important roles in metabolic pathways that lead to the production of lignin, phenols, phytoalexins, and other defense-related molecules. Many of these pathways use enzymes that require the micronutrients manganese (Mn), copper (Cu), zinc (Zn), molybdenum (Mo), or boron (B) as cofactors or activators. Other elements such as potassium (K) and chlorine (Cl) influence osmotic relations, water cycling, and root exudation, which, in turn, influence beneficial microbes. Indirect mechanisms include effects on soil medium nitrification, rooting medium pH, and chemical transformation of micronutrients.

Below, each element's effect on plant disease is discussed, but caution must be exercised in that nutrition must be viewed holistically, because all nutrients affect the uptake and function of other elements and can ultimately increase or decrease plant susceptibility to disease.

Nitrogen

Nitrogen is the fourth most abundant element in plants and is an essential component of amino acids, enzymes, hormones, phenolics, phytoalexins, and proteins, all of which can have direct effects on disease development. The amount of N applied can have immediate effects on a plant disease, relative to the nutritional requirement of the plant (**Table 1**). The greatest responses are generally in the range from deficiency to physiological sufficiency. Nitrogen-deficient plants may not provide the nutrient environment necessary for obligate pathogens, whereas excess N may inhibit the production of defense responses to other pathogens (Huber, 1980; Huber and Watson, 1974).

The time of application can also have striking effects on disease development. Side-dressing nitrogen can compensate for early-season losses caused by leaching and denitrification but, more importantly, can avoid the early-season seedling diseases that accompany nitrogen application, such as damping-off caused by species of *Rhizoctonia* or *Pythium*. However, caution should be exercised as mechanical damage made to the roots from side dressing may increase root rots. Many times the choice as to when to apply nitrogen can be influenced by disease pressure. For example, delaying N application

Table 1 Influence of nitrogen form on plant disease

Disease or disorder	*Pathogen or causal agent*	*Host*	*NH_4*	*NO_3*
Aflatoxin	*Aspergillus flavus* group	Corn and peanut	D	–
Anthracnose	*Gnomonia leptostyla*	Black walnut	D	D
Black root rot	*Thielaviopsis basicola*	Tobacco	D	I
Black root rot	*Rhizoctonia fragariae*	Strawberry	D	I
Blast	*Magnaporthe grisea*	Rice	D	I
Blossom-end rot	Physiological disorder	Tomato	I	–
Brown patch	*Rhizoctonia solani*	Ryegrass	D	–
Club Root	*Plasmodiophora brassicae*	Cabbage	D	–
Corky root	*Pyrenochaeta lycopersici*	Tomato	I	I
Crown rot	*Rhizoctonia solani*	Beets	I	D
Crown and root rot	*Fusarium oxysporum*	Tomato	I	D
Eyespot	*Pseudocercosporella herpotrichoides*	Wheat	I	D
Leaf blight	*Erwinia chrysanthemi*	Chrysanthemum	I	I
Leaf spot	*Alternaria macrospora*	Cotton	D	–
Lesion nematode	*Pratylenchus penetrans*	Strawberry	D	I
Mummy berry	*Monilinia vaccinii-corymbosi*	Blueberry	D	–
Nematodes	*Criconemella* spp.	Turfgrass	–	I
Root rot	*Fusarium oxysporum* and *Fusarium proliferatum*	Asparagus	I	D
Root rot	*Phytophthora parasitica*	Tomato	–	I
Root rot	*Fusarium* spp.	Pea	I	D
Root rot	*Thielaviopsis basicola*	Pansy	D	I
Root and stem rots	*Sclerotium rolfsii*	Many plants	D	D

Abbreviations: D, decrease; I, increase; – no effect.

Source: Adapted from Huber, D.M., Thompson, I.A., 2007. Nitrogen and plant disease. In: Datnoff, L.E., Elmer, W.H., Huber, D.M. (Eds.), Mineral Nutrition and Plant Disease. St. Paul, MN: American Phytopathological Society, pp. 31–44.

in winter wheat until spring can result in early N deficiency and increase susceptibility of plants to take-all root rot caused by *Gaeumannomyces graminis* (Sacc.) Arx & D. Olivier var. *tritici* (J. Walker) (Huber and McCay-Buis, 1993). However, a fall application can impose excess N availability during cold, wet winter periods and increase susceptibility to *Rhizoctonia* root rot (Huber, 1989).

The rate of nitrogen also affects disease susceptibility. Excessive nitrogen is well documented to increase the severity of *Botrytis* blight on numerous greenhouse plants (Dik and Wubben, 2007; Yermiyahu *et al.*, 2006). Root diseases are similarly exacerbated under high nitrogen rates. Root rot of wheat caused by *Fusarium culmorum* (Papendick and Cook, 1974) and *Pythium* root of geraniums (Gladstone and Moorman, 1989) are more severe under high nitrogen regimes. Although growers pay close attention to rates of nitrogen applied, most do not recognize the role that form of nitrogen may play in enhancing or suppressing disease. Nitrogen is the only nutrient that is available as both a negatively charged ion, nitrate (NO_3^-) and a positively charged ion, ammonium (NH_4^+). Nitrate N and NH_4-N are metabolized differently in plants and can have opposite effects on diseases. In fact, many of the conflicting research reports regarding the role of nitrogen in plant disease may be due to a failure to recognize and report the form of nitrogen used in the experiments. Interestingly, the form of nitrogen can have striking effects on the effectiveness of biological control. Borrero *et al.* (2012) observed suppression of *Fusarium* wilt of tomato with *Trichoderma* spp. but only under increasing concentrations of NH_4-N. Suppression from *Trichoderma* spp. was minimal under the nitrate regime.

Many of the underlying mechanisms governing disease suppression with different nitrogen forms relate to soil pH (Smiley and Cook, 1973). Nitrate N increases the pH of the rooting medium and NH_4-N lowers pH, making both the bulk soil and rhizosphere more acidic. These effects occur through microbial and chemical reactions in the soil as well as root-mediated ion exchanges near the roots. Acidification of the root zone also solubilizes oxides of zinc, copper, manganese, and iron, which increases their availability for uptake. As discussed below, these micronutrients can play pivotal roles in disease suppression. When the nitrogen form is applied as nitrate, *Fusarium* wilts and root rots of asparagus, basil, beets, carnation, chrysanthemum, cyclamen, gladiolus, tobacco, tomatoes, and watermelon are reported less severe than when applied as NH_4-N (**Figure 1**; Elmer, 1997; Huber and Thompson, 2007). Our understanding of this phenomenon relates to the effect on rhizosphere pH, root exudation, and the availability of Fe to microbes (Jones and Woltz, 1970).

The opposite is true for diseases caused by *Gaeumannomyces* spp., *Thielaviopsis* spp., and *Verticillium* spp. where NH_4-N suppresses disease and NO_3-N favors it. Take-all root rot of wheat caused by *G. graminis* can be suppressed in the field by supplying nitrogen in the ammoniacal form, such as NH_3, $(NH_4)_2SO_4$, NH_4Cl, and $(NH_4)_2PO_4$ (Huber, 1989; Reis *et al.*, 1982). Ammonium sulfate suppressed take-all patch of turfgrass but was more effective when combined with other cultural practices for disease control (Dernoeden, 1987). The effects of NH_4-N occur through chemical reactions in the soil as well as root-mediated ion exchanges near the roots that, in turn, increase the availability and uptake of micronutrients and promote beneficial microbes in the rhizosphere.

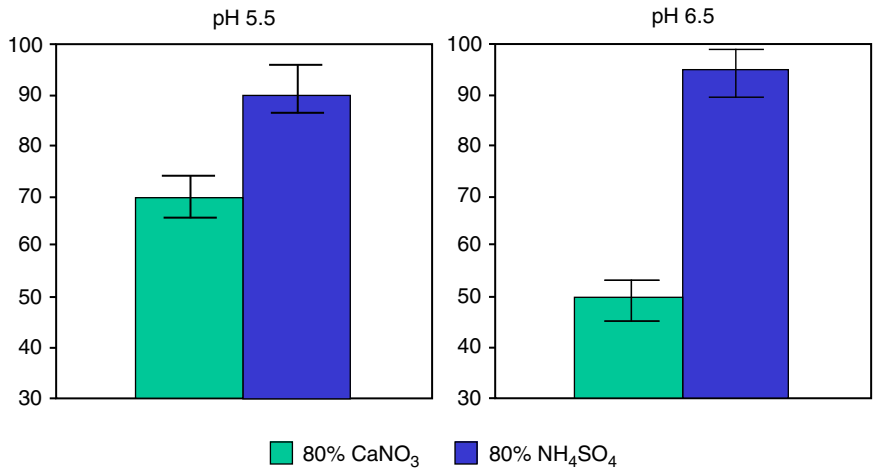

Figure 1 Effect of N form and soil pH on percentage of tomatoes with *Fusarium* wilt. Data from Jones, J.P., Woltz, J.P., 1970. *Fusarium* wilt of tomato: Interaction of soil liming and micronutrient amendments on disease development. Phytopathology 60, 812–813.

Managing soil acidity with NH_4-N has become an important strategy for managing black root rot caused by *Thielaviopsis basicola* on tobacco and ornamentals. On eggplant, *Verticillium* wilt was suppressed and yields were increased by 20% when NO_3-N was replaced with NH_4-N (Elmer and Ferrandino, 1994). In strawberry, the black root rot complex caused by *Rhizoctonia fragariae* and the lesion nematode, *Pratylenchus penetrans*, was reduced by the application of ammonium sulfate, but not with calcium nitrate fertilizer (Elmer and LaMondia, 1999a,b). Plants treated with ammonium sulfate had more yield, more leaf area, more runners, and higher tissue levels of K, S, Mn, and Zn than strawberries treated with calcium nitrate.

It is very common for N to interact with other nutrients. Potassium increases uptake of NO_3 and promotes the synthesis of organic N compounds, whereas phosphorus and chlorine decrease NO_3 uptake and enhance the uptake of NH_4. Ammonium and Cl increase the uptake of manganese (Mn). Manganese is required for NO_3 assimilation and protein synthesis. Molybdenum (Mo), magnesium (Mg), iron (Fe), ascorbic acid, and energy are required for the reduction of NO_3 to NH_4. Growers should also pay attention to the ion that accompanies the nitrogen salt.

Phosphorus

Phosphorus (P) is the second component listed in the analysis of fertilizers due to its vital role in cell division, energy transfers, and its regulatory role for transport of sugars within the plant. Although there are exceptions, most reports on P and plant disease suggest that increasing phosphorus above that necessary for proper growth may be associated with increased disease. In fact, those cases where P reduced disease may have been in situations where the element was deficient. Cases where the disease became worse following P application might have been in soils where excess P decreased the availability of other elements that, in turn, increased the plant's susceptibility. In acidic soils, P reacts with Fe, Al, and Mn to form insoluble products, making P less available. In alkaline soils, P reacts with Ca and reduces P availability. Therefore, maintenance of soil pH is very important to maximize availability of P and promote root health.

Another important consideration is the role of beneficial mycorrhizal fungi in P nutrition and disease development. These fungi form a symbiotic relationship with the plant's roots known as mycorrhizae that improve plant health and reduce disease damage. Many crops have mycorrhizal associations that are likely interrupted during propagation cycles. If mycorrhizae are present or have been established on roots, there may be a need to alter the P applications because mycorrhizal associations can be inhibited by increased P availability. Commercial applications of mycorrhizal fungi are available and may have value in management of soilborne disease. Their use may allow other nutrients to be more available as added P could lead to the precipitation of other elements.

Foliar applications of phosphorous acid (H_3PO_3), or its salts (also referred to as phosphonate, phosphate, and phosphonic acid), may inhibit plant pathogens from the fungal-like Oomycota, i.e., species of *Phytophthora* and *Pythium* (Brunings *et al.*, 2012). The inhibiting effect from phosphorous acid is probably due to either an inhibition of the metabolic activity of the pathogen or a direct toxic effect on the pathogen. Phosphorous acid has been demonstrated to control a number of plant diseases, including downy mildew, late blight of potato and tomato, foliar blights on peppers and cucurbits, root and stem rots, and damping off.

Potassium

Potassium (K) plays many essential roles in plant nutrition. Although K is not structurally bound in the plant, it increases root growth, improves water and nutrient uptake, increases cellulose and protein content, reduces lodging, enhances and regulates at least 60 different plant growth enzymes, and can affect the occurrence of a plant disease (Prabhu *et al.*, 2007).

Potassium alone or its combination with N, P, and other nutrients can alter the disease severity of many soilborne and

Table 2 Effect of potassium on plant disease development

Pathogen Group	*Number of articles showing the effect of potassium on disease*[a]			
	Decreased	*Increased*	*No effect*	*Total*
Fungal	89	33	8	130
Bacterial	19	5	*	24
Viruses	9	5	3	17
Nematodes	3	6	1	10

*Data not available.

foliar plant pathogens. These have been extensively reviewed before for a number of crops, diseases, and pathogens (Prabhu *et al.*, 2007; Huber, 1980). Even though no generalization can be made on the effect of K on disease development, this element is reported to decrease the intensity of many diseases caused by pathogenic fungi, bacteria, viruses, and nematodes (**Table 2**). Unfortunately, in many of these studies, investigators have failed to give adequate consideration to the companion anions, nutrient balance, and nutrient status in order to determine a definitive role of K (Prabhu *et al.*, 2007). Thus, there may be a greater response to K in deficient than fully sufficient plants or with an excess of K beyond that required for nutrient sufficiency. This suggests that K may affect host resistance more as opposed to a direct effect on the pathogen.

Some rice genotypes are more efficient than others in K uptake, and this may contribute to their increased disease resistance and higher grain yield (Fageria *et al.*, 1990). Several diseases increase with an increase in N and the effect of K can be directly correlated with the level of N. The critical factor affecting rice blast caused by *Pyricularia oryzae* is the N:K ratio in leaves. Blast severity is low when there is a high tissue K:N ratio, whereas a high N:K ratio increases blast. When the concentration of N is low, the addition of K suppresses rice blast. However, when the level of N is high, the addition of K increases blast. The K and N ratio greatly influences plant growth as well as disease development, and the ratio may change with growth of the plant.

Although the physiological function of K in disease resistance mechanisms is not well understood, nutritional factors favoring host plant resistance have been attributed to alterations in protein or amino acid availability, decreased cell permeability, or decreased susceptibility of tissue to maceration and penetration (Prabhu *et al.*, 2007). Arginine increases as the level of K increases and resistance of potato plants to late blight (*Phytophthora infestans)* increases as the levels of K increases due to the accumulation of fungistatic levels of arginine in leaves. Exudates of arginine inhibit germination of sporangia of *P. infestans* and exudation is lowest in the absence of K when N and P are high. The ability of various soil-applied or foliarly applied K salts, such as potassium phosphonate, K_2HPO_4, KH_2PO_4, and KNO_3, to stimulate systemic acquired resistance in susceptible plants against powdery mildews, anthracnose, rust, and several other pathogens suggests that fundamental changes in physiological pathways are probably important in disease resistance (Reuveni *et al.*, 2000; Becot *et al.*, 2000; Orober *et al.*, 2002). Anatomical changes affected by K nutrition may also play an important role in disease resistance. Enhanced silicification of cell walls by K is one explanation for increased disease resistance. A deficiency of K decreases Si accumulation in epidermal cells and increases the susceptibility of rice to leaf blast. Potassium, in combination with P, induces the development of thicker cuticles and cell walls that function as mechanical barriers to infection by several pathogens or limit the growth of some pathogens as a result of a higher proportion of sclerenchyma tissue (Huber, 1980).

Fertilizer sources of K include various salts from which the anion may also manifest an effect on disease in combination with or independent of the K ion. The more common sources of K fertilizers include the chloride (muriate) or sulfate salts; however, carbonate, nitrate, phosphate (mono- and dibasic), silicon, and various organic salts are also used. It is difficult to distinguish between the effect of the K and the anion in the fertilizer salt used for disease management unless many combinations are studied. It is well known that the Cl anion can affect various diseases independent of K (Elmer, 2007) and that K influences plant uptake of nitrate, Ca, and other mineral elements. Similar interactions are observed with phosphate salts of K (Lopez and Lucas, 2002). The level of K in plants depends on the availability of Mg and Ca. Calcium alters the Ca:K ratio and interacts with other elements. The function of K in cellular organization and permeability is complimented by large Ca reserves in mature plant tissue. Calcium enhances K availability in neutral soils, but not in acidic soils. An interaction between K and Mg was demonstrated on rice leaf blast; blast increased when K was applied alone but could be reduced by adding Mg.

Calcium

Calcium (Ca) is the third most abundant nutrient in most plant species. Calcium concentrations in plant tissues are usually twice that of magnesium. Because both nutrients are cations with a double positive charge, they often antagonize and interact with each other in nutrient management programs.

Calcium is extremely important in normal cell growth where it forms the glue between cell walls, i.e., Ca-polygalacturonates are needed for the middle lamella for cell wall stabilization. This element may act as a secondary messenger; consequently, it plays a role in many enzymatic reactions involved in early plant defense mechanisms (Huber *et al.*, 2012). Calcium is commonly applied as $CaCl_2$, $CaSO_4$, or $Ca(NO_3)_2$.

Many previous studies investigating the role of $Ca(NO_3)_2$ credited all of the plant disease suppression to the NO_3 component and failed to recognize the calcium ion. Unfortunately, most studies do not examine different sources of Ca and its companion anion to demonstrate the contribution of calcium to plant disease control. A study on roses found that foliar applications of $CaCl_2$ reduced the incidence of gray mold (*Botrytis cinerea)*. Calcium applications to carrot infected with *Sclerotium rolfsii* reduced damage and increased yield. Many times the influence of Ca on soil pH is more important than the actual concentration of Ca in soil. For example, a reduction in the incidence of cavity spot of carrot by *Pythium coloratum* was achieved with lime, whereas gypsum ($CaSO_4$), which does not affect pH, applied to the same soil at the same rate had no effect on the incidence of disease. The role of pH and Ca in suppressing clubroot of cabbage caused by *Plasmodiophora brassicae* was recognized in 1878, and liming of the soil for control of clubroot has been practiced for more than 200 years. The severity of *Fusarium* wilt of tomato caused by *Fusarium oxysporum* f. sp. *lycopersici* is also reduced with calcium applications. Greenhouse and field experiments in Florida showed that amending *Fusarium*-infested soil with gypsum ($CaSO_4$) did not increase the soil pH and did not reduce the occurrence of tomato *Fusarium* wilt, whereas the Ca content of tissues of plants grown in soil amended with hydrated lime ($Ca(OH)_2$) was increased and did reduce the occurrence of wilt.

Spraying calcium salts, such as $CaCl_2$ and $Ca(NO_3)_2$, on tomatoes reduced powdery mildew colonies. A study on roses found that foliar applications of $CaCl_2$ reduced the incidence of gray mold (*B. cinerea*). The same study found that increasing Ca concentrations in the soil improved the shelf life of the flower. Calcium may also influence the spread of *Phytophthora* spp. in water; vinca plants that were flood irrigated and then infected with *Phytophthora* spp. were healthier when the complete fertilizer solution was amended with $Ca(NO_3)_2$. Other studies demonstrated that calcium applied as either $CaCl_2$ or $Ca(NO_3)_2$ in water or in Ca-free soluble fertilizer solutions suppressed the release and the motility of the swimming spore. These results demonstrate the urgent need to understand more about how calcium amendments interfere with *Phytophthora* in recirculating irrigation systems.

Magnesium

Magnesium (Mg) is usually applied as $MgSO_4$ or $MgCl_2$ and has been associated with both increased disease and suppression of plant disease (Jones and Huber, 2007). Of 46 studies investigating the role of magnesium on plant disease, 22 found that this nutrient decreased disease, 18 found that it increased disease, and 6 found that there was little or no difference. As the data are so conflicting, no real patterns can be discerned. As a consequence, there is a paucity of information regarding the direct effects of Mg on plant pathogenesis. It may be that some of these studies corrected a magnesium deficiency and the result was a healthier plant with more vigor and disease resistance. When Mg was applied in excess of what is required for normal growth, a nutritional imbalance developed that promoted plant stress and more disease. The few examples on ornamentals may illustrate this point. The addition of extra magnesium to potting soil was associated with increased damping-off of calendula. However, when carnations were grown on calcareous soils, applications of Mg suppressed *Fusarium* wilt. The latter study was likely a result of the added magnesium correcting a deficiency due to the high Ca concentration.

Chlorine

Chlorine has been routinely applied to crops as chloride (Cl), which served as a companion ion for NH_4-N, K, and Ca fertilizers. Chloride was thought to have little value in improving plant growth because Cl was thought to be highly available in soils and not essential. Yet reports of chloride deficiency in more than 11 economic crops have been published (Engel *et al.*, 1997; Fixen, 1993; Gausman *et al.*, 1958). The role of Cl in plant disease management has also long been misunderstood (Elmer, 2007). The benefits of Cl are still mistakenly being ascribed to the accompanying cation. For example, although it is well documented that proper K nutrition will suppress some plant diseases, many subsequent studies that examined different forms of K found that the ameliorating effects on disease were restricted to KCl amendments, suggesting that Cl was the active ion.

Nutritionally, Cl is regarded as a micronutrient, yet, as in the case of Ca, benefits are achieved with rates that far exceed the plant's nutritional requirements. Monocots tend to be more tolerant of high amounts of chloride. High rates of Cl salts have marked effects on inhibiting soil nitrification, enhancing availability of Mn and other micronutrients, and on increasing beneficial microorganisms.

As an element, Cl^- is the only inorganic anion that is not structurally bound to a metabolite. Its major role is to serve as a charge-balancing ion. When a cell absorbs Cl^-, it accumulates in the cell vacuole and lowers the cell water potential below that of the medium surrounding the cell. Water then flows into the cell and increases hydrostatic cell pressure so that it maintains a pressure that exceeds the force exerted by the plasmalemma. The cells remain turgid and are able to grow even when drought conditions prevail. Theoretically, plants that get root diseases might be protected by supplying sufficient Cl so that they could still grow normally in soils with greater moisture deficits. Studies are needed to validate this theory. Chloride ions also alter the quantity and quality of organic solutes that are exuded into the rhizosphere, thus reducing the germination of and infection by root pathogens. Another major role of Cl in disease suppression comes from its effect on increasing the availability of Mn, which has direct effects on host resistance.

Most reports that demonstrate disease suppression with chloride fertilization have been conducted on monocots, but there are many notable studies where crop health was advanced on dicots (**Table 3**; Maas, 1986; Fixen, 1993). Plants such as asparagus, barley, beets, celery, and coconut evolved near coastlines (Bailey and Bailey, 1976) and acquired tolerance or even preference for chloride in their nutrition. It appears that chloride nutrition may have its greatest benefits to the host in providing tolerance to stresses such as drought and

Table 3 Host plants, diseases, and pathogens suppressed by chloride salts

Host plant	*Disease*	*Pathogen(s)*
Asparagus	*Fusarium* crown and root rot	*Fusarium oxysporum* *Fusarium proliferatum*
Barley	Common root rot	*Bipolaris sorokiniana Fusarium culmorum*
	Powdery Mildew	*Erysiphe graminis* f. sp. *hordei*

disease. For asparagus, NaCl applications increased fern vigor and spear yields by 15–30% in plots affected by *F. oxysporum* f. sp. *asparagi* and *Fusarium proliferatum*, but there was no evidence that NaCl improved growth in healthy plantings (Reid *et al.*, 2001). Barley had less common root rot caused by *Bipolaris sorokiniana* (Goos *et al.*, 1989; Timm *et al.*, 1986) when plants were fertilized with chloride. Kettlewell *et al.* (1990) observed suppression of powdery mildew of wheat caused by *Erysiphe graminis* f. sp. *tritici* and brown rust of barley caused by *Puccinia hordei*, when plants were sprayed with KCl. As adequate K was found in the soil, it was concluded that a potassium deficiency was unlikely.

Elmer (1997) found that applications of NaCl, KCl, $CaCl_2$, and $MgCl_2$ were equal in suppressing *Rhizoctonia* root rot of table beets, caused by *Rhizoctonia solani*. Yields were increased in infested soil when NaCl (560 kg ha^{-1}) was applied in an NH_4-N regime, but not in an NO_3-N regime (Elmer, 1997). Alternatively, Schneider (1985) found that the effectiveness of chloride in suppressing *Fusarium* yellows of celery was enhanced in an NO_3-N regime and in the presence of adequate potassium. Both studies demonstrate the complexities of chloride nutrition and its interaction with other elements.

Chloride fertilization contributes to a range of physiological and soil chemical responses. Although Cl applied at high concentrations may have a minor toxic effect on the pathogen, most soilborne pathogens grew better in culture as the chloride concentration increased by 0.5–1.0% (Firdous and Shahzad, 2001; Suleman *et al.*, 2001). Other processes that act through the soil environment, host physiology, or microbial community are more probable mechanisms for disease suppression. Chloride affects nitrification (Christensen *et al.*, 1986), manganese availability (Krishnamurti and Huang, 1992), and osmoregulation (Kettlewell *et al.*, 2000; Schneider, 1990). It has also been associated with enhancing biological control (Amir *et al.*, 1996; Elmer, 1995). Scientists at Oregon State University suspected that chloride was affecting water relations in wheat (Christensen *et al.*, 1981; Powelson and Jackson, 1978). Using pressure chambers to measure leaf water potential (ψ leaf) and thermocouple psychrometry to measure osmotic potential (ψ osmotic) in cell sap, they observed lower leaf water potentials and lower osmotic potentials in leaves treated with NH_4Cl than in leaves fertilized with $(NH_4)_2SO_4$. Turgor potential (ψ pressure), calculated from the formula ψ leaf$=\psi$ osmotic$+\psi$ pressure, was often greater in Cl-treated plants. Elmer and LaMondia (1999a,b) similarly monitored the water potential of ferns of NaCl-treated asparagus plants and found that NaCl applications significantly lowered the predawn fern water potential and increased the estimated turgor potential. Kettlewell and colleagues (Kettlewell *et al.*, 2000; Mann *et al.*, 2004) also found that KCl applications reduced the osmotic potential of the wheat leaves and prevented the germination of spores of *E. graminis*. These studies implicated chloride in reducing the osmotic potential of cell sap. The optimal water potential for most

plant-infecting fungi is less than −0.5 mPa, and the growth rates of most of them are reduced by 50% when the water potential decreases to −3.0 mPa. There are exceptions. For example, *F. culmorum* prefers an osmotic potential of −0.8 to −1.2 mPa. Complete inhibition of many pathogens occurs at −5.0 to −10 mPa (Cook and Papendick, 1972). The reduced growth of the pathogen before the onset of pathogenesis would play an important role in reducing disease. Schneider (1990) advanced a theory that chloride ions are used by plants to tolerate the osmotic up-shocks that plant cells encounter when plant water potential is abruptly altered. In the absence of chloride ions, root cells manufacture organic ions, such as organic acids and amino acids, to maintain charge balance. Schneider (1990) argued that when plant water potential is altered by irrigation or changes in irradiation, organic solutes are quickly exported to the root apoplast to maintain a pressure potential within the root cells. These organic compounds would, in turn, act as nutrition for root pathogens before pathogenesis. When chloride was applied, plants would need to produce less organic and amino acids for charge balance. Roots would export chiefly chloride ions of low nutritional value in their exudates. The concept of altered root exudation, as proposed by Schneider (1990), may explain changes in microbial communities in the rhizosphere. The possible role of beneficial microbes in chloride-treated wheat plants was proposed by Halsey and Powelson (1980) and Christensen *et al.* (1981). Chloride fertilization of neutral soils has also been associated with changes in the microbial community (Amir *et al.*, 1996; Elmer, 1995, 2003). Elmer (1995) isolated bacteria from NaCl-treated asparagus plants and found greater densities of beneficial fluorescent pseudomonads. It is reasonable to assume that the effect of chloride in reducing osmotic potential also affects water cycling and root exudations. In later split root studies, Elmer (2003) reported that NaCl application to asparagus decreased root exudation of malic acid and amino acids, increased Cl ions, and increased fluorescent pseudomonads on the nontreated side of the root system. Thus, chloride had a root-mediated effect on the microbial community.

The ability to increase Mn also could increase host resistance by favoring the deposition of ligneous defense barriers following infection. The synthesis of these products requires many reactions in the shikimic acid pathway that contain enzymes activated by manganese.

Sulfur

Sulfur (S) is an essential element and a component of proteins and is the oldest recorded fungicide in use on vegetables and other crops. The fungicidal effect of elemental S was discovered in the early 1800s and has been widely used in agricultural production since the end of the nineteenth century (Hoy, 1987). Elemental S proved to be most efficient against rust and powdery mildew (Coleno, 1987; Cook, 1987; Hoy, 1987) but was also successfully used against other diseases, such as downy mildew in cereals (Hoy, 1987) and common scab of potato (Vlitos and Hooker, 1951). However, the significance of soil-applied S on plant disease only recently became evident when S deficiency symptoms were noted following the drastic decrease of SO_2 emissions from coal-burning facilities (Haneklaus *et al.*, 2007). Most growers do not consider S nutrition as a component in their fertility programs. However, it is frequently applied as $NH_4(SO_4)_2$, Ca_2SO_4, or $MgSO_4$. These salts are almost exclusively applied with the aim of supplying the cations N, Ca, or Mg. When manipulation of pH is the sole objective, elemental S and $AlSO_4$ are often used. On field crops, several studies have shown that proper sulfur nutrition can induce resistance to plant pathogens through its effect on the function and availability of S-containing amino acids. Under controlled conditions in a greenhouse experiment, Wang *et al.* (2003) found that disease severity of oilseed rape infected with *Sclerotinia sclerotiorum*, corn infected with *Bipolaris maydis*, and winter wheat infected with *Rhizoctonia cerealis* was significantly decreased when the S supply was increased to young plants. Under the conditions of S deficiency in field experimentation, soil-applied S fertilization significantly reduced the infection of oilseed rape with light leaf spot (*Pyrenopeziza brassicae*), of grapes with powdery mildew (*Uncinula necator*), and of potato with stem canker (*R. solani*; Schnug *et al.*, 1995; Klikocka *et al.*, 2003). Soil-applied S reduced the infection rate and disease severity of *R. solani* on potato tubers by 41% and 29%, respectively (Klikocka *et al.*, 2003).

Sulfur-induced resistance runs parallel to other defense mechanisms, which are activated after fungal attack so that a clear differentiation is difficult, particularly under field conditions. The S-containing amino acids cysteine, methionine, and glutathione play roles in protein synthesis of many defense products.

In addition, salicylic acid as well as H_2O_2 initiates and maintains systemic resistance, and the accumulation of salicylic acid is linked to S metabolism (Haneklaus *et al.*, 2007). As air quality improves and atmospheric S decreases further, growers will need to be more attentive to S nutrition.

Micronutrients

The metals iron, manganese, zinc, copper, molybdenum, boron, and nickel have diverse but essential roles in plants, functioning as cofactors or activators of enzyme systems, as previously mentioned in the section on Cl. Many of these enzyme systems play pivotal roles in disease resistance through the production of defense products, including key roles in phenol metabolism and lignin biosynthesis. In general, the concentrations that correct visual deficiency symptoms in plants are often far below the levels needed to ensure proper plant health and defense against a plant disease. Most micronutrients become less available as the pH rises so growers should be aware that although a crop species may favor alkaline soil and may not show deficiencies, it may be more susceptible to attack from plant pathogens. One quick method to correct aboveground deficiency symptoms and boost resistance to foliar diseases is to apply a foliar application of the needed micronutrient(s). However, as micronutrients are not translocated to the roots, this application would not suppress a root disease. Below is a more comprehensive discussion of each element's role in plant disease suppression.

Iron

Iron (Fe) nutrition not only boosts plant vigor and health, it indirectly affects disease development in the root zone where its unavailability may limit the growth of pathogens (Expert, 2007). One of the major roles where Fe influences plant disease is through siderophores, which are synthesized and excreted by certain microorganisms to acquire their iron and thereby rob other microorganisms of Fe in the rhizosphere (Buyer *et al.*, 1994; Crowley and Gries, 1994; Marschner, 1995). Siderophores are low molecular weight molecules (<1500 Da) that possess a high affinity for Fe^{3+}. They specifically capture Fe^{3+} ions and transport them back into the microorganism that produces them. However, the siderophores can also release their Fe^{3+} ions to iron-deficient plants. Therefore, it seems possible that microbial siderophores present in soils increase Fe availability on the root surface, depending on their different chemical, physical, and absorptive characteristics. Mechanisms involved in these processes have, however, been poorly defined.

In addition to exploitation of microbial siderophores by plant roots, there are other beneficial effects of siderophore-producing rhizobacteria on plant growth. Specific *Pseudomonas* strains called plant growth promoting rhizobacteria (PGPR) are able to enhance the growth of plants. Application of these microbes can result in significant yield increases and were attributed entirely or in part to competition for Fe with pathogenic microorganisms (Schroth and Hancock, 1982). In fact, several strains of *Pseudomonas fluorescens* are effective in biocontrol of plant diseases due to their ability to deny available Fe to pathogenic bacteria or fungi. However, siderophore-mediated biocontrol activity of rhizosphere *Pseudomonas* species is affected by the availability of Fe in the rhizosphere. The rhizosphere needs to be Fe limiting to maximize the biocontrol potential that, in turn, may limit its overall use in biocontrol. Another mechanism of biocontrol by rhizobacteria is induced systemic resistance (ISR). Siderophores produced by bacteria might induce ISR. Leeman *et al.* (1996) and Buysens *et al.* (1996) both found that ISR against plant disease was governed by determinants regulated by Fe availability.

Another critical aspect concerns the signaling role of Fe in plants and plant-associated microorganisms. The cellular and molecular regulatory mechanisms controlling the genes involved in Fe uptake, trafficking, and storage are still unclear. Elucidating these issues may eventually help to develop strategies in plant disease management. Nevertheless, it should be recognized that biotechnological approaches targeting isolated components within complicated metabolic pathways are limited in their application.

Manganese

A rich body of information exists on the role of manganese (Mn) nutrition in suppressing a plant disease (Thompson and Huber, 2007). Manganese in plants is absorbed in the reduced Mn^{2+} form and is poorly mobile in mature leaves but slightly mobile in root and stem tissue. However, the availability of Mn in soil is influenced most strongly by soil pH and microbial activity (Gilkes and McKenzie, 1988; Norvel, 1988). At soil pH below 5.2 or above 7.8, Mn becomes chemically available or unavailable, respectively. Its availability between these ranges is largely influenced by the Mn-transforming microbes. For this reason, soil microbes, especially bacteria and fungi, have a profound effect on the global cycling of Mn and its availability for plant uptake (Elmer, 1995; Erhlich, 1996; Ghiorse, 1988; Tebo *et al.*, 1997). It has been demonstrated, for example, that Mn-oxidizing microbes can decrease Mn availability by up to five orders of magnitude (Brouwers *et al.*, 2000; Tebo *et al.*, 1997).

It has long been noted that certain environmental conditions that affect Mn availability has the same effects on disease, such as pH, N form, organic matter, moisture status, soil temperature, and microbial activity (Huber and Wilhelm, 1988). One obstacle to increasing Mn levels in plants is its lack of mobility. Foliarly applied Mn is not basipetally translocated to roots. Furthermore, soil-applied Mn can be rapidly immobilized by oxidizing soil organisms. It is not always possible to override the biological and environmental factors affecting Mn availability and utilization (Graham and Webb, 1991).

Potential mechanisms of controlling disease with Mn have not been totally resolved. Manganese affects the production of many host defense products. Manganese functions primarily as an activator of enzymes, including dehydrogenases, tranferases, hydroxylases, and decarboxylases (Burnell, 1988). Fundamentally, Mn serves as an activator of several enzymes in the shikimic acid pathway for production of important secondary metabolites that lead to the production of phenolics, cyanogenic glycosides, and the deposition of ligneous defense barriers (Burnell, 1988). The role of Mn in carbohydrate, nitrogen, and secondary metabolism indirectly affects disease (Graham, 1983; Huber, 1989). More directly, Mn can reduce growth of the pathogen, which may explain why these organisms evolved mechanisms for oxidizing Mn to unavailable forms.

Zinc

Zinc (Zn) nutrition is associated with important plant defense pathways against fungal, bacterial, viral, and nematode pathogens (Siddiqui *et al.*, 2002). Zinc protects plant cells from toxic oxygen radicals and plays an important role in the production of disease resistance signaling proteins. Zinc has direct effects on fungal growth and secondary metabolism and indirect effects on host susceptibility. Zinc strictly modulates fungal accumulation of citric acid, stimulates glucose uptake, and pigment and antibiotic production by microbes (Duffy, 2007).

Zinc nutrition has pronounced effects on root diseases. Tomato diseases caused by *Macrophomina phaseolina*, *Fusarium solani*, and *R. solani* and charcoal rot of maize caused by *M. phaseolina* were all reduced by increasing soil concentrations of Zn (Siddiqui *et al.*, 2002; Pareek and Pareek, 1999). In-furrow treatment with a mixture of zinc oxide (ZnO) and zinc sulfate ($ZnSO_4$) reduced the incidence of powdery scab of potato, caused by *Spongospora subterranea* f. sp. *subterranea* (Falloon *et al.*, 1996). Zinc soil amendments reduced the severity of maize smut, caused by *Ustilago maydis*, and the effect was increased with nitrogen fertilizers (Kostandi *et al.*, 1997). Maize grain yields were correspondingly increased.

Zinc influences the biocontrol activity of many bacteria. Amendment of Zn soil amendments improved the activity of *Pseudomonas aeruginosa* against *M. phaseolina*, *F. solani*, and *Meloidogyne javanica* on tomato, even though they exhibited little direct effect on root disease or galling and zinc-deficient soils supported higher populations of *P. aeruginosa* (Siddiqui *et al.*, 2002). The role of Zn in microbial interactions involves biocontrol of *Fusarium* with *Pseudomonas*. Duffy and Défago (1997) showed that the biocontrol activity of *P. fluorescens* CHA0 against *Fusarium* root rot of tomatoes was enhanced in the presence of Zn with increased production of the antibiotic 2,4-diacetylphloroglucinol. The effect was mediated by a Zn-induced inhibition of fusaric acid by the pathogen that can, in turn, inhibit the antibiotic. Another example where Zn indirectly influences biological control is for pathogenic strains of *R. solani* that produce phenylacetic acid (Siddiqui and Shaukat, 2003, 2005). This metabolite can inhibit the production of nematicidal compounds by *P. fluorescens* when damaged by root knot nematode (*Meloidogyne incognita)* and is greater when *R. solani* is present. However, when sufficient Zn was present, phenylacetic acid production by *R. solani* was decreased, which relieved the repression of nematicidal compounds and resulted in enhanced biocontrol of the nematode.

Copper

The recognition of the inhibitory effect that copper (Cu) has on microorganisms has made it a common component of many pesticides, whereas its role in plant physiological and host defense reactions that influence disease resistance or susceptibility has received much less attention (Graham, 1983; Graham and Webb, 1991). The reduction of foliar diseases with soil-applied Cu and benefits from Cu applied at subbiocidal rates are evidence of increased plant resistance rather than a direct effect on the pathogen (Graham, 1983; Graham and Webb, 1991; Shabranskii *et al.*, 1984). Copper-activated physiological processes also increased the resistance of hops to downy mildew (Shabranskii *et al.*, 1984). The system where Cu nutrition has made the striking difference is in barley. Low levels or deficiency of Cu causes pollen sterility, which reduces yield and predisposes plants to ergot (Azouaou and Souvré, 1993; Graham, 1975) by causing the normally closed flowers of wheat and barley to open, exposing them to infection by *Claviceps purpurea* (Mantle and Swan, 1995).

Copper affects plant disease by three known mechanisms. Direct toxicity as a bactericide or fungicide is the most common one. However, the effects of Cu on plant resistance and pathogen virulence can also operate simultaneously. For example, Cu is an essential cofactor in various enzyme systems involved in plant defense against infection, the production of antimicrobial compounds, and general disease resistance (Graham, 1983; Graham and Nambiar, 1981; Graham and Webb, 1991; Lebeda *et al.*, 2001). Copper chloride induces the activity of chalcone synthase, a key enzyme in the biosynthesis of diverse flavonoids involved in plant disease resistance (Harker *et al.*, 1990). Amino oxidases involved in H_2O_2 production in cell walls in response to attack of pea by *Ascochyta rabiei* (Pass.) Labrousse required Cu (Laurenzi *et al.*, 2001).

Copper is an essential micronutrient for pathogens as well. Copper deficiencies in *Colletotrichum lindemuthianum* can result in the pathogen becoming avirulent to bean. Copper-containing laccases can be important virulence factors for many plant-pathogenic fungi, enabling them to degrade physical barriers and detoxify phytoalexins and tannins (Mayer and Staples, 2002). For example, *Heterobasidion annosum* declined in aggressiveness as laccase levels decreased (Johansson *et al.*, 1999). Integrated research involving Cu with other defense-stimulating approaches could enhance the effectiveness of many cultural management strategies for disease control.

Molybdenum

Molybdenum (Mo) is not associated with influencing plant disease like other elements. A few studies show an increase in disease, but an equal numbers show no effect (Graham and Stangoulis, 2007). Suppression of *Verticillium* wilt of tomato by treatment of roots with molybdenum has been reported (Dutta and Bremner, 1981) along with a study by de Jesus *et al.* (2004), who reported that application of Mo 25 days after sowing beans suppressed angular leaf spot, caused by *Phaeoisariopsis griseola*.

The best-known role of Mo involves nitrogen metabolism and its role in activating the nitrate reductase enzyme, which may then influence disease development. In addition, heavy metals like Mo are effective in deactivating viruses by denaturing protein coats (Verma and Verma, 1967), killing zoospores of *Phytophthora* sp. (Halsall, 1977) and inhibiting nematodes (Haque and Mukhopadhyaya, 1983). However, at this point, manipulating Mo nutrition has not been demonstrated to be an effective strategy for disease management.

Boron

The role of boron (B) nutrition in plant disease is through its wide ranging effects on structural and metabolic processes that control plant defense (Stangoulis and Grahm, 2007). In general, B deficiency leads to host susceptibility by compromising the plant's ability to manufacture lignin and phenolic compounds that are necessary for inhibiting pathogen invasion. When B fertilizers are used in these situations, plant health and disease suppression are increased. Much of the role of B in disease suppression is yet to be investigated.

Nickel

The role of nickel (Ni) as an essential mineral element for higher plants is a relatively recent discovery (Brown *et al.*, 1987). Its low requirement in plants qualifies it as a piconutrient rather than a micronutrient, yet deficiencies are observed on a wide variety of plants (Wood and Reilly, 2007). Nickel deficiency is increased when root knot nematodes are present. These observations indicated an adverse influence of nematodes on Ni nutrition of plants. Given that a wide range of physiological processes are disrupted by insufficient Ni nutrition, Ni may be a missing link in certain recalcitrant

disorders affecting several crop species that suffer from replant disorders associated with pathogenic nematodes or fungi.

Beneficial Elements (Silicon and Aluminum)

As stated above, not all elements are viewed as essential, but a growing body of research has shown that many nonessential elements can suppress a number of plant diseases. It is interesting that the ameliorating effects of these elements are frequently only realized when the plant is under a biotic stress, such as a plant disease that, once again, implicates their influence in host defense mechanisms.

Plants that accumulate silicon (Si) have shown enhanced resistance to a number of foliar and root diseases in both dicots and monocots (Datnoff *et al.*, 2007c). Silicon is absorbed by roots as monosilicic acid, $Si(OH)_4$, and most plants accumulate this element in great quantities (between 1% and 10% of their dry weight). The availability of silicon to plants varies depending on the soil. Tropical/subtropical soils highly weathered, low in base saturation, and acidic are known to be low in plant-available silicon. Organic and sandy soils also contain low levels of silicon. Further, soilless mixes are silicon deficient. Consequently, plants grown on these types of rooting media may benefit from a silicon application. Many agronomic and horticultural crop plants supplied with silicon may gain protection from pathogenic fungi, bacteria, nematodes, and viruses (**Table 4**). Silicon appears to affect a number of components of host plant resistance that includes delaying the incubation and latent period and reducing lesion expansion rates, lesion size, and lesion number (Seebold *et al.*, 2001). Subsequently, disease progress and final disease severity is dramatically reduced, and the resistance of susceptible cultivars is augmented to almost the same level as those with complete or partial resistance (Seebold *et al.*, 2000; Rodrigues *et al.*, 2001). Silicon may even suppress plant disease as effectively as a fungicide (Resende *et al.*, 2013; Seebold *et al.*, 2004). As the silicon concentration (insoluble or soluble) increases in plant tissue, plant disease suppression greatly improves.

The underlying mechanisms that govern disease protection are still not well understood; however, the effect of silicon on plant resistance to disease is considered to be due to either an accumulation of absorbed Si in the epidermal tissue or an expression of pathogenesis-mediated host defense responses (Datnoff *et al.*, 2007c). Accumulated monosilicic acid polymerizes into polysilicic acid and then transforms to amorphous silica, which forms a thickened Si cellulose membrane. By this means, a double-cuticular layer protects and mechanically strengthens plants. Silicon also might form complexes with organic compounds in the cell walls of epidermal cells, thus increasing their resistance to degradation by enzymes released by fungi.

Research also points to the role of silicon *in planta* as being active, and this suggests that the element might be a signal for mediating defense reactions to plant diseases (Belanger *et al.*, 2003; Rodrigues *et al.*, 2003). Silicon has been demonstrated to stimulate chitinase activity and rapid activation of peroxidases and polyphenoxidases after fungal infection. Glycosidically bound phenolics extracted from Si-amended plants when subjected to acid or β-glucosidase hydrolysis displayed strong fungistatic activity (Cherif *et al.*, 1994). More recently, flavonoids and momilactone phytoalexins, low molecular weight compounds that have antifungal properties, were found to be produced in both dicots and monocots, respectively, fertilized with Si and challenged inoculated by the pathogen in comparison with nonfertilized plants also challenged inoculated by the pathogen (Fawe *et al.*, 1998; Rodrigues *et al.*, 2004). These antifungal compounds appear to be playing an active role in plant disease suppression. In addition, an increase in superoxide (O^-) generation was observed in rice leaves of plants treated with silicon 15 min after inoculation with *Magnaporthe grisea* (Maekawa *et al.*, 2002). Rodrigues *et al.* (2005) showed that β 1–3 glucanase, peroxidase, and PR-1 proteins are associated with rice blast suppression. Both these studies suggest that other additional mechanisms may be involved in silicon-mediated resistance to plant diseases. Recently, genome-wide studies for tomato, rice, and wheat amended with silicon and compared with nonamended control plants have shown a differential expression of a large number of genes, and these genes are known to be involved in host plant defense mechanisms or metabolism (Brunings *et al.*, 2009; Chain *et al.*, 2009; Ghareeb *et al.*, 2010).

Given the low silicon content now being found in a number of soil types and its role in enhancing disease resistance, it seems prudent to consider soluble silicon supplementation as amendments as simple, inexpensive methods to reduce plant diseases.

Recent research has shown that aluminum (Al) is similarly taken up in plants at low levels and may be important to plant health (Shrew *et al.*, 2007). It has been a long-held practice to lower root medium pH with $AlSO_4$, which is often accompanied by reductions for many plant diseases caused by *Verticillium* and *Thielaviopsis*. However, evidence may suggest that the aluminum ion is partially responsible for suppression of disease through its effect on the germination of fungal spores in soil. Applications of different forms of Al to peat soils at pH 4 and 6 were followed by reductions in the population densities of *Phytophthora parasitica*. Strategies for incorporating Al in disease management need to be developed.

Summary

There is no question that proper nutrient management has marked effects on plant diseases. Nutrients influence the plant pathogen both directly and indirectly by controlling the pathogen's rate of germination, penetration, colonization, and reproduction; affecting the infection rate or the progress of disease; and having a toxic effect (Datnoff *et al.*, 2007b). In addition, nutrients promote plant vigor, aiding recovery from infection, and change the anatomical or physiological plant state by thickening the cuticle or changing biochemical reactions. Hence, these nutritional practices often serve as the first line of defense against the occurrence of plant disease. However, the strategy of using fertilization practices as a management strategy against disease needs to be developed for each crop species.

This article highlights a few examples where manipulating fertilization reduced disease. Another more important goal

Table 4 Host, disease, and plant pathogen response to silicon applications

Host	*Disease*	*Pathogen*	*Effect*[a]
Monocots			
Rice	Leaf and neck blast	*Magnaporthe grisea*	⊕
	Brown spot	*Cochliobolus miyabeanus*	⊕
	Sheath blight	*Thanathephorus cucumeris*	⊕
	Leaf scald	*Monographela albescens*	⊕
	Stem rot	*Magnaporthe salvinii*	⊕
	Grain discoloration	Many fungal species	⊕
	Bacterial leaf blight	*Xanthomonas oryzae pv. oryzae*	⊕
	Root knot nematode	*Meloidogyne* spp.	⊕
Wheat	Powdery mildew	*Blumeria graminis*	⊕
	Leaf blotch	*Septoria nodorum*	⊕
	Foot rot	*Fusarium* spp.	⊕
	Leaf spot	*Phaeosphaeria nodorum*	⊕
	Eye spot	*Oculimacula yallundae*	⊕
	Brown foot rot	*Fusarium culmorum*	∅
	Brown rust	*Puccinia recondita*	∅
	Sorghum Anthracnose	*Colletotrichum graminicola*	⊕
Barley	Black point	*Alternaria* spp.	⊕
	Powdery mildew	*Erysiphe graminis* f.sp. *hordei*	⊕
Rye	Powdery mildew	*Erysiphe graminis*	⊕
Sugarcane	Brown Rust	*Puccinia melanocephala*	∅
	Ring spot	*Leptosphaeria sacchari*	⊕
Zoysiagrass	Leaf blight	*Rhizoctonia solani*	⊕
Creeping bentgrass	Root rot	*Pythium aphanidermatum*	⊕
	Brown patch	*Rhizoctonia solani*	⊕
	Dollar spot	*Sclerotinia homoeocarpa*	⊕
Kentucky bluegrass	Powdery mildew	*Sphaerotheca fuliginea*	⊕
Bermudagrass	Leaf spot	*Bipolaris cynodontis*	⊕
St. Augustine-grass	Gray leaf spot	*Magnaporthe grisea*	⊕
Corn	Stalk rot	*Pythium aphanidermatum* and *Fusarium moniliforme*	⊕
	Corn smut	*Ustilago maydis*	⊕
Dicots			
Tomato	*Fusarium* wilt	*Fusarium oxysporum* f.sp. *lycopersici* (races 1 and 2)	∅
	Fusarium crown and root rot	*Fusarium oxysporum* f.sp. *radicis-lycopersici*	⊕/∅[b]

Source: Adapted from Datnoff, L.E., Rodrigues, F.A., Seebold, K.W., 2007c. Silicon and plant disease. In: Datnoff, L.E., Elmer, W.H., Huber, D.M. (Eds.), Mineral Nutrition and Plant Disease. St. Paul, MN: APS Press, pp. 233–246.

was to underscore how nutrient management could advance a major strategy for disease control and how that could have an immediate impact on agriculture and food systems. Unfortunately, the fractionation of the data has hindered development of a working plan for disease management. Most experimental studies tend to focus on one plant, one element, and one disease in isolation of other variables, so most research provides only 'snapshots' of information. The dearth of experimental data, combined with the gigantic number of agronomic and horticultural crop species whose fertility requirements differ widely from each other, makes the development of this strategy a daunting task.

Growers are encouraged to consider their fertility regimes and nutrient management plans against the aforementioned information and make adjustments first on a small scale, then expand as the results warrant. Researchers are encouraged to explore a crop's horticultural and disease response to a wide array of elements applied in many combinations. The role that each nutrient plays in disease must be viewed in the greater context of its numerous interactions with other elements, the host plant, root medium, and with beneficial and pathogenic microorganisms.

Glossary

Agroecosystem Ecosystem arbitrarily defined as a spatially and functionally coherent unit of agricultural activity, and includes the living and nonliving components involved in that unit as well as their interactions. The basic unit of study for an agroecologist.

Ecological infrastructure The way natural capital stocks are organized to produce ecosystem goods and services.

Ecosystem services The direct and indirect contributions of ecosystems to human well-being.

Natural capital The stocks of natural assets (e.g., soils, forests, and water bodies) that yield a flow of valuable ecosystem goods or services now and into the future.

Natural resource management The management of natural resources, including soils, land, water, animals and plants, for the production of goods to meet changing human needs, while simultaneously ensuring the long-term productive potential of these resources and the maintenance of their environmental functions.

Soil (1) The unconsolidated mineral or organic material on the immediate surface of the earth that serves as a natural medium for the growth of land plants. (2) The unconsolidated mineral or organic matter on the surface of the earth that has been subjected to and shows effects of genetic and environmental factors of: climate (including water and temperature effects), and macro- and microorganisms, conditioned by relief, acting on parent material over a period of time. A product soil differs from the material from which it is derived in many physical, chemical, biological, and morphological properties and characteristics.

Introduction

Population growth and the need to obtain energy and food from the planet's finite resources are intensifying pressures on natural ecosystems that are required for life support. This increasingly raises questions about the sustainability and viability of agricultural systems into the future, and one's ability to mitigate the impacts of ongoing production gains on the environment. Much of the current economic growth strategy is based on the false assumption that natural resources, such as land and water, are inexhaustible, which they are not, raising the question of the long-term viability of the current economic model (Munda *et al.*, 1994). A recent report to the United Nations "Building a Sustainable and Desirable Economy-in-Society-in-Nature" (Costanza *et al.*, 2012) stated that new economic models and agricultural systems are needed, "that respect planetary boundaries and recognize that the ultimate goal is sustainable human well-being and not growth of material consumption" (Rockström *et al.*, 2009).

In his latest book Brown (2012) argued that "food is the new oil and land is the new gold." He identifies major pressures on agroecosystems, which threaten food security globally. These include increasing soil erosion, desertification, salinity, and the expansion of urban areas over the best and most versatile soils. Despite the fact that land is continually being lost to urbanization, the total area under cultivation continues to rise, with new arable and pasture lands being created, often at the expense of forests. Demand for agricultural land continues to increase in line with population growth. This has resulted in the clearing of marginal land that is more susceptible to degradation.

The Millennium Ecosystem Assessment (MEA, 2005) was a wakeup call for the society, because it highlighted the link between ecosystems and human well-being (**Figure 1**), and elucidated the rapidity with which ecosystems are being degraded, as well as the associated social and economic impacts of environmental degradation. The MEA generated sufficient concern about the health of the natural ecosystems to lead many governments and international agencies to seek out a less destructive and more sustainable way forward. There is widespread agreement that if ecologically sustainable development is to be achieved, one must both protect some

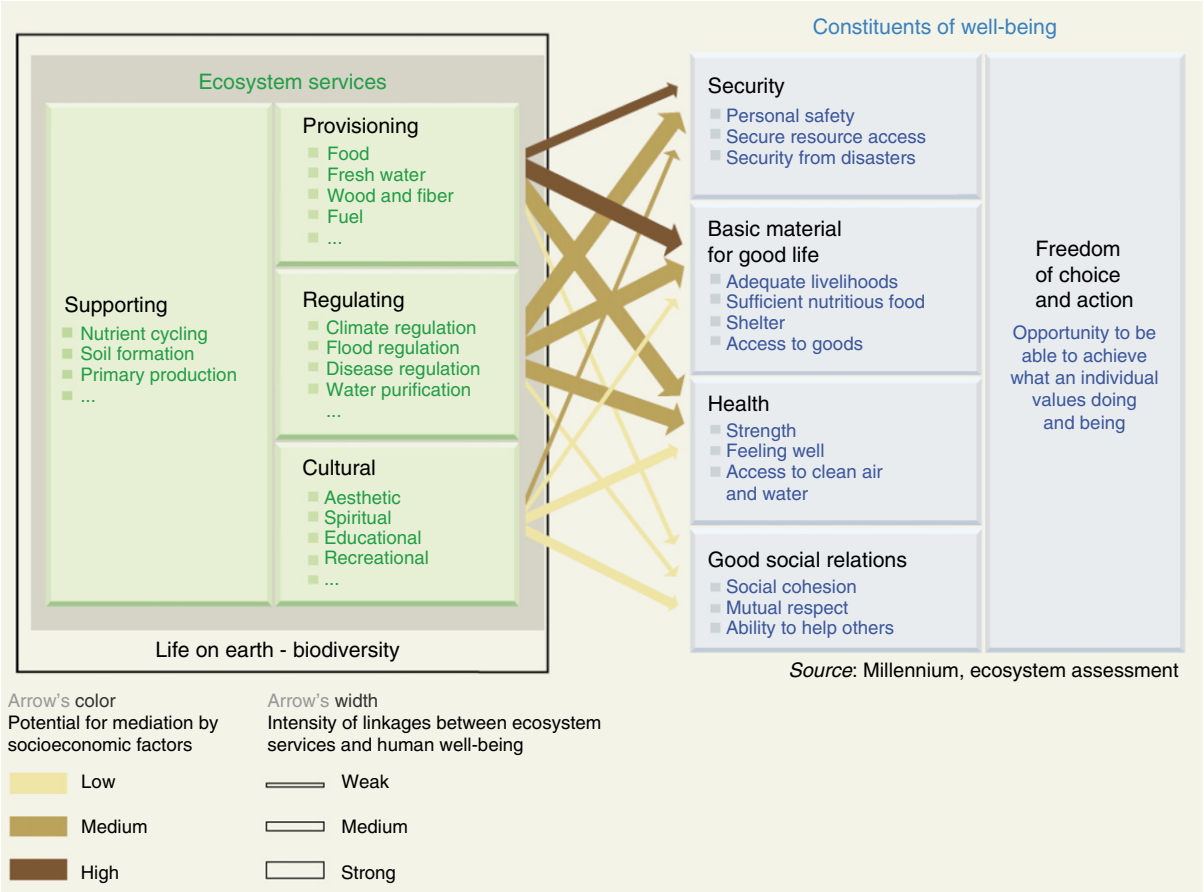

Figure 1 Millennium ecosystem assessment framework for ecosystem services. Reproduced from MEA, 2005. Millennium Ecosystem Assessment: Ecosystems and Human Well-being: Synthesis. Washington, DC: Island Press.

ecosystems from development, and find better ways of managing those one uses for production. The 'ecosystems approach' to natural resource management (NRM) focuses on how to better manage the natural resources (Convention on Biological Diversity (CBD) principles of the ecosystem approach). It accomplishes this by recognizing the wide range of benefits that one obtains from the harvested goods and ecosystem services they deliver through better representing the value of ecosystem services in decision-making frameworks and indicators of progress (Robinson *et al.*, 2013).

The major challenge for agroecosystems is to shift from management of a single function, namely production, to management that meets multifunctional goals of production and land stewardship. This challenge is becoming more widely recognized, for example, in the European Union Common Agricultural Policy (CAP), where reforms are slowly transitioning away from a focus on production only to a broader land stewardship and ecosystem service delivery approach to provide additional services, including clean water or increased biodiversity. Intensive use of agricultural land for food production can result in soil degradation and declining biodiversity, thus limiting the provision of ecosystem services. The challenge for future agricultural production is to limit and mitigate degradation processes, while maintaining and even increasing yields. The economies of nations worldwide rely on the sustainability of agroecosystems. As history has shown, entire civilizations can be lost if agroecosystems collapse (Diamond, 2005; Hillel, 1991; Montgomery, 2007).

To create more multifunctional agroecosystems, new frameworks and tools are needed to enable resource managers and policy makers to more holistically quantify the ecological value of natural resources, and thus enable more informed decisions on trade-offs. Research in agronomy, soil science, and the hydrological and environmental fields also needs to adapt to the changing policy landscape that the ecosystem services approach to sustainable development brings (Bouma, 2005; Daily, 1997; Robinson *et al.*, 2013).

The ecosystem services approach and associated discipline of Ecological Economics bring a new set of terminology to agriculture and agricultural systems, giving it a more economic feel. Ecosystems are conceptualized as 'natural capital,' as distinct from manufactured and human capital, and the functions of ecosystems that benefit society are termed 'ecosystem services.' These concepts have gained considerable traction in NRM research and policy making over the past decade. Resource management frameworks based on ecosystem services approaches are being adopted and promoted

by many international organizations including: the Conference of the Parties to the CBD, the Food and Agriculture Organization of the United Nations, The Organization for Economic Cooperation and Development, the United Nations Environment Programe (UNEP), and the United Nations Development Program (Robinson *et al.*, 2013). The concept of ecosystem services is the foundation for international initiatives, such as the Millennium Ecosystem Assessment (MEA, 2005), The Economics of Ecosystems and Biodiversity (TEEB, 2010) initiative, and the Intergovernmental Panel on Biodiversity and Ecosystem Services (Marris, 2010).

This article examines the concepts of natural capital, ecological infrastructure, and ecosystem services in the context of agroecosystems, with a focus on soil. The article provides a brief history of the origin of the concepts, their modern use, and how they are being adapted to agroecosystems. It then discusses some major challenges associated with the further development of these concepts for future research and use in NRM.

Origin of the Concepts

In the second half of the twentieth century, some environmentally aware economists (Schumacher, 1973) and ecologists (Westman, 1977) began to highlight the societal and economic benefits one obtains from ecosystems. The economists started to analyze environmental problems in economic terms in order to point out the dependence of human societies on natural ecosystems (de Groot, 1987, 1992). They stressed that the undervaluation of the contributions of ecosystems to public welfare and economic growth was due in part to the fact that many ecosystem services are public-owned and consequently not adequately quantified in terms comparable with economic indicators (Braat and de Groot, 2012; Costanza *et al.*, 1997). To ensure sustainability, they argue that the critical nonmarketed contributions of ecosystems underpinning human economies need to be explicitly incorporated in economic decision making.

An emerging discipline, ecological economics (Costanza, 1991; Costanza *et al.*, 2012), sees global economies as a subsystem of the larger finite global ecosystem. Economies exchange energy, materials, and waste flows with the social and ecological systems with which they coevolve (Braat and de Groot, 2012; Martinez-Alier, 2001). Ecological economists question the sustainability of the existing economy, because environmental impacts are not internalized and raw material and energy are not seen as finite resources (Martinez-Alier, 2001). One of the main focuses of ecological economics is to develop biophysical indicators and indices of sustainability (Costanza, 1991) and include the environment in macroeconomic accounting. Following the trend set by environmental economics, ecological economics uses concepts from conventional neoclassical, or welfare economics, and expands them to include environmental impacts, ecological limits, finite natural resources, and issues of equity and scale as necessary requirements for increasing the sustainability of human activities (Martinez-Alier, 2002). Ecological economics acknowledges the reality of entropy, and emphasizes the dependence of economic systems on social systems, and of social systems on ecological systems. Foundational concepts include natural capital, ecosystem services, and ecological infrastructure (see Sections Natural Capital, Ecological Infrastructure, and Ecosystem Services).

Natural Capital

Natural capital refers to the extension of the economic idea of manufactured capital to include environmental goods and services. The first documented usage of the term in this context can be traced back to at least as early as 1837 (Robinson *et al.*, 2012). In the twentieth century, William Vogt pioneered the idea of natural capital in his book, 'Road to Survival' (Vogt, 1948). In it he wrote, "By using up our real capital of natural resources, especially soil, we reduce the possibility of ever paying off the debt" (Mooney and Ehrlich, 1997, p. 44). Costanza and Daly (1992) went on to define natural capital as "stocks of natural assets (e.g., soils, forests, and water bodies) that yield a flow of valuable ecosystem goods or services into the future". This concept was brought into prominence by the landmark paper by Costanza *et al.* (1997) who defined it as 'the stock of materials or information contained within an ecosystem.' Natural capital, like all other forms of capital, is a stock as opposed to a flow, but the idea of information, connection, and organization of stocks (Robinson *et al.*, 2009) is being increasingly associated with the concept. Natural capital stocks can move around the earth-system and can be equated, for example, with the goods one harvests from nature, termed by Costanza *et al.* (2012) as 'stock-flows.' The interaction between stocks forms the basis of the flow of emergent ecosystem services that Costanza *et al.* (2012) termed 'fund-services,' because they arise from the fund of stocks. A major difference between neoclassical and ecological economists is that neoclassical environmental economists mostly embrace what is termed a 'weak sustainability' approach, which assumes substitutability between natural and manufactured capital, for example, substituting soil nutrients from mineral weathering with fertilizer, whereas ecological economists generally advocate the 'strong sustainability' approach, which maintains that natural capital and manufactured capital are complementary rather than substitutable (Costanza and Daly, 1992).

Ecological Infrastructure

Ecological systems are complex and interconnected. Interactions between organisms and their environment take place at multiple and nested scales. Amplifying feedbacks and counterbalancing loops occur within and between scales, and thresholds and tipping points separate alternative stable states of systems (Walker *et al.*, 2006). These many and varied interactions can be simply referred to as 'connectivity.' Connectivity in the ecological sense includes both quantity (number) and quality (strength, direction, and duration) of connections. This notion is recognized by some authors (Costanza *et al.*, 1997; Costanza *et al.*, 2012; Dominati *et al.*, 2010a,b; Robinson *et al.*, 2009) using the natural capital concept, but its importance cannot be overstated. A holistic

conception of nature links natural capital and ecosystem services within a framework that explicitly accounts for ecological connectivity. It must go beyond simple 'stocks and flows' and depict a supply chain that ultimately delivers ecosystem services required for human well-being.

The concept of 'infrastructure,' which is defined as 'the underlying foundation, or framework, of a system' (American Heritage Dictionary, 2009), is robustly applicable to both ecological and socioeconomic systems. The term 'ecological infrastructure' was introduced and elaborated in government policy reports in 1977 and 1981 in the Netherlands (Van Selm, 1988b). In this earliest usage, ecological infrastructure was related to the design of structures that would enable many species to move between the 'islands' of natural environments that were left remaining among the 'oceans' of agricultural land (Van Selm, 1988a). The term ecological infrastructure has continued to be used as a design concept for the incorporation of ecological features, such as 'corridors' and 'networks' into human infrastructure design (Morrish, 1995; Xuesong and Hui, 2008). However, some authors are now suggesting that ecological infrastructure can also be used to depict an underlying framework that supports the terrestrial and aquatic ecosystems producing clean air, clean water, and biodiversity that is critical to the resilience and regenerative capacity of natural and human systems alike (Quinn and Tyler, 2007; Postel, 2008).

The essential feature of the underlying framework of ecological infrastructure is connectivity (Arthington *et al.*, 2006; Soule *et al.*, 2004; Ward and Stanford, 1995). Maintaining ecological connectivity is the key to ecosystem health and integrity, and a certain level of ecological integrity is required for the continued production of ecosystem services that are essential for human well-being. The relationship between natural capital, ecological infrastructure, and ecosystem services can be conceptualized as 'Ecological infrastructure is how natural capital stocks are organized to produce ecosystem goods and services' (Bristow *et al.*, 2010; **Figure 2**). Being the source of ecosystem services, ecological infrastructure also provides the 'sink' for the wastes produced by socioeconomic systems (**Figure 2**).

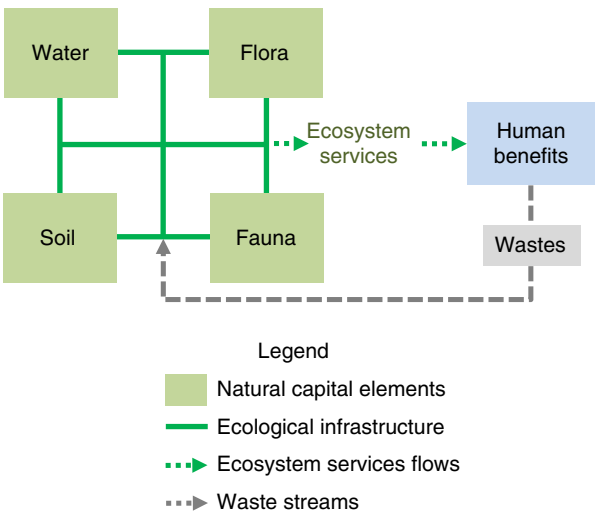

Figure 2 The relationship between natural capital, ecological infrastructure, and ecosystem services.

Ecosystem Services

The origin of the concept of ecosystem services is to be found within work from the 1970s (Braat and de Groot, 2012; Gomez-Baggethun *et al.*, 2010). Mooney and Ehrlich (1997) trace the first usage of 'Nature's services' to a report from 1970 entitled, 'Study of Critical Environmental Problems,' but the paper by Westman (1977) is strongly associated with the development of modern-day ecosystem service concepts. Proponents of the modern-day ecosystem services approach argue that the functions of ecosystems beneficial to society must be accounted for in economic decision making to increase the sustainability of human activities (Braat and de Groot, 2012). References to ecosystem services in the professional literature have grown exponentially since 1990 (Costanza and Daly, 1992; Daily, 1997; de Groot, 1992). In the late 1990s, much of the focus was on methods to estimate the economic value of ecosystem services (Costanza *et al.*, 1997; Hanley and Spash, 1993; Patterson, 1998).

The definition of ecosystem services continues to evolve from:

- The conditions and processes through which natural ecosystems, and the species that make them up, sustain, and fulfill human life (Daily, 1997).
- The benefits human populations derive, directly or indirectly, from ecosystem functions (Costanza *et al.*, 1997).
- The benefits people obtain from ecosystems (MEA, 2005).
- Components of nature, directly enjoyed, consumed, or used to yield human well-being (Boyd and Banzhaf, 2007).
- The aspects of ecosystems utilized (actively or passively) to produce human well-being (Fisher *et al.*, 2009).
- The direct and indirect contributions of ecosystems to human well-being (TEEB, 2010).
- To the final contributions that ecosystems make to human well-being – Common International Classification of Ecosystem Services (CICES, 2013).

The definition by the MEA (2005) is regarded by many as a simple and appropriate working definition of the concept. The increasing acceptance of the importance of ecosystem services in policy-making circles over the past two decades has resulted in the development of general typologies and classification systems, which characterize the diversity of roles played by ecosystems. De Groot's classification system (1992) was one of the first. It defined ecosystem functions as "the capacity of natural processes and components to provide goods and services that satisfy human needs, directly or indirectly" and grouped these functions into four primary categories:

- Regulation functions to regulate essential ecological processes and life support systems and the maintenance of ecosystem health,
- Habitat functions to provide refuge and reproduction habitat to wild plants and animals,

- Production functions for processes creating living biomass used for human consumption (food, raw materials, energy resources, and genetic material),
- Information functions to provide opportunities for reflection, spiritual enrichment, cognitive development, recreation, and esthetic experience.

The paper by Costanza *et al.* (1997) on the total value of global ecosystem services was a milestone in the mainstreaming of ecosystem services (Braat and de Groot, 2012). It detailed seventeen goods and services, including most of de Groot's (1992) functions. The monetary figures presented had a profound impact on both science and policy communities. The paper generated strong support as well as fervent criticism (Toman, 1998), and it marked the start of a notable increase in the development and use of monetary valuation concepts for NRM in parallel with the ongoing development of ecosystem services quantification.

Daily (1997) produced an ecosystem services framework including five services:

- Production of goods: Food, pharmaceuticals, durable materials, energy, industrial products, and genetic resources;
- Regeneration processes: Cycling and filtration processes and translocation processes;
- Stabilizing processes: Regulation of hydrological cycle, stabilization of climate, and coastal and river channel stability;
- Life-fulfilling functions: Esthetic beauty, cultural, intellectual, and spiritual inspiration;
- Preservation of options: Maintenance of the ecological components and systems needed for future.

De Groot *et al.* (2002) identified 23 functions in the four primary categories established in earlier work (de Groot, 1992) and detailed the corresponding processes and services, noting that "ecosystem processes and services do not always show a one-to-one correspondence" (de Groot *et al.*, 2002, p. 397). To the four categories, they later introduced a fifth, a carrier function and specified that the "regulation functions provide the necessary preconditions for all other functions" (de Groot, 2006, p. 177). Ekins *et al.* (2003) used a similar classification to argue that the principles of environmental sustainability must be based on the maintenance of the important life-support 'functions of nature' that form the basis on which the 'functions for people' are fundamentally dependent.

The novel idea that de Groot *et al.* (2002) and Ekins *et al.* (2003) advanced in their frameworks was that some ecosystem functions – or processes – support others. The Millennium Ecosystem Assessment (MEA, 2005) took up this idea in a 'framework of ecosystem services' (**Figure 1**). The MEA was conducted under the umbrella of the UNEP. It studied the state and relevance of ecological systems for society, and introduced the concept of ecosystem services to a global audience. The MEA assessed the consequences of ecosystem change for human well-being, and defined ecosystem services as "the benefits people obtain from ecosystems" (MEA, 2005, p. 40). The MEA framework classified ecosystem services into four categories:

- Provisioning services, the products obtained from ecosystems;
- Regulating services, the regulation of ecosystem processes;
- Cultural services, obtained from ecosystems through spiritual enrichment, cognitive development, reflection, recreation, and esthetic experiences;
- Supporting services, those that are necessary for the production of all other ecosystem services.

The first three categories of services directly affect people, whereas the supporting services maintain the other services and life support. The approach set out in the MEA has since been adopted and used widely (Barrios, 2007; Lavelle *et al.*, 2006; Sandhu *et al.*, 2008; Swinton *et al.*, 2007; Zhang *et al.*, 2007).

The MEA was followed by The Economics of Ecosystems and Biodiversity study (TEEB, 2010), which was also carried out under the UNEP umbrella. The TEEB study aimed at providing more comprehensive data and understanding of the economic significance of the loss of ecosystem services and the consequences of policy inaction. The TEEB study took a clear economic approach to facilitate the adoption of an ecosystem services approach in policy making. This was brought about by increasing research on the monetized value of ecosystem services, and the associated increasing interest of policy makers in designing market-based instruments (e.g., payments for ecosystem services and economic incentives for conservation) to affect change (Braat and de Groot, 2012). In the TEEB framework, an extension of the so-called cascade model (Haines-Young and Potschin, 2009) was presented (**Figure 3**). Here ecosystem services are placed between the natural and human systems. This framework also separates services from human benefits and their economic values. A benefit is not a service. It is the advantage one receives from a good or service.

A further refinement that has emerged from the development and discussion of these typologies is the differentiation between 'intermediate' processes (analogous to the MEA supporting services) and 'final' services (Boyd and Banzhaf, 2007; Fisher *et al.*, 2009). This refinement stems from the need to differentiate between intermediate products and final products in welfare economics accounting to avoid double counting. The United Kingdom's national ecosystem assessment (Watson and Albon, 2011) adopts this differentiation, focusing on the delivery of final services. Ecosystem services are undoubtedly becoming an increasingly influential tool, but adoption of the concept is constrained by the confusion surrounding the definition of terms and the limited number of practical examples of application. The quantitative relationships between ecosystem components and ecosystem processes, functions, and service delivery are still poorly understood in many areas, and conceptual frameworks continue to be refined.

An Ecosystem Approach for the Management of Agroecosystems

The CBD laid down 12 principles to guide an ecosystems approach (**Table 1**). These principles are highly anthropocentric, as they focus on management and decision making. The strong emphasis on management is of particular relevance to agroecosystems, as is the recognition of the need to manage

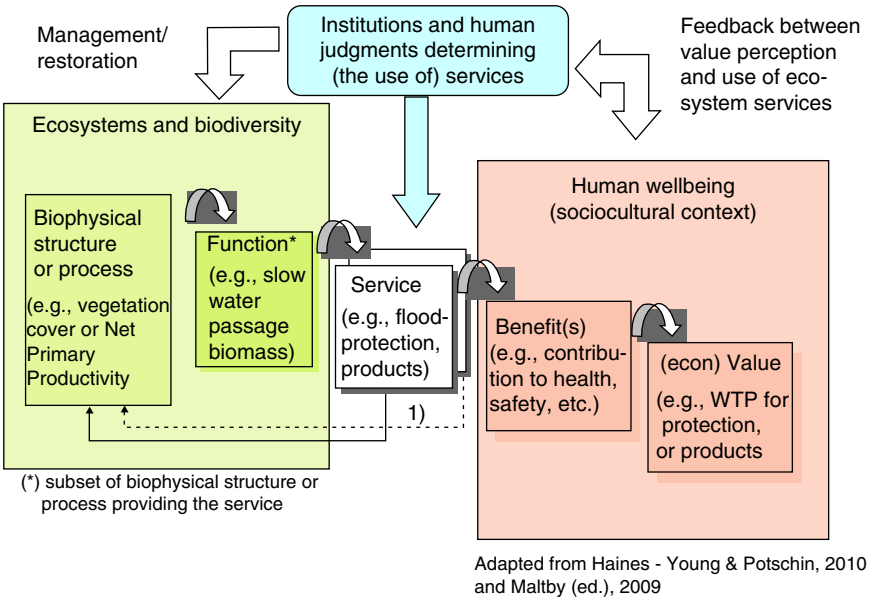

Figure 3 The Economics of Ecosystems and Biodiversity framework for ecosystem services: The pathway from ecosystem structure and processes to human well-being. WTP, Willingness to pay. Reproduced from Figure 1.4 in TEEB, 2010. The economics of ecosystems and biodiversity: Mainstreaming the economics of nature: A synthesis of the approach, conclusions and recommendations of TEEB. Available at: www.teebweb.org (accessed June 2013).

Table 1 Convention on biological diversity: Twelve principles of the ecosystem approach

Principle 1	The objectives of management of land, water, and living resources are a matter of societal choices
Principle 2	Management should be decentralized to the lowest appropriate level
Principle 3	Ecosystem managers should consider the effects (actual or potential) of their activities on adjacent and other ecosystems
Principle 4	Recognizing potential gains from management, there is usually a need to understand and manage the ecosystem in an economic context. Any such ecosystem-management program should: a. Reduce those market distortions that adversely affect biological diversity b. Align incentives to promote biodiversity conservation and sustainable use c. Internalize costs and benefits in the given ecosystem to the extent feasible
Principle 5	Conservation of ecosystem structure and functioning, in order to maintain ecosystem services, should be a priority target of the ecosystem approach
Principle 6	Ecosystems must be managed within the limits of their functioning
Principle 7	The ecosystem approach should be undertaken at the appropriate spatial and temporal scales
Principle 8	Recognizing the varying temporal scales and lag-effects that characterize ecosystem processes, objectives for ecosystem management should be set for the long term
Principle 9	Management must recognize that change is inevitable
Principle 10	The ecosystem approach should seek the appropriate balance between, and integration of, conservation and use of biological diversity
Principle 11	The ecosystem approach should consider all forms of relevant information, including scientific and indigenous and local knowledge, innovations, and practices
Principle 12	The ecosystem approach should involve all relevant sectors of society and scientific disciplines

ecosystems in a socioeconomic context to maintain ecosystem services provision, via balancing the conservation of resources with their use (Robinson *et al.*, 2013). The power to choose the outcomes of ecosystem management, but not necessarily the means, rests with society. In addition, it is recognized that change is inevitable, which is a growing area of interest within Soil Science, with respect to understanding how human activity is causing soil change on anthropogenic time scales (Richter *et al.*, 2011).

International initiatives, such as The Economics of Ecosystems and Biodiversity, (TEEB, 2010) and the United Nations initiative 'The Economics of Land Degradation' (September 2011) have embraced an ecosystems approach, using the concepts of natural capital and ecosystem services as their framework for addressing sustainable land management. The ecosystems approach is also reflected in the European Union's strategy for land management in the CAP. In 2007, the European Commission published the Thematic Strategy for

Soil Protection, which identified a specific policy need to address the threats to soils, including the protection of the essential soil functions and ecosystem services that they provide. A number of international projects are now working on strategies to embed ecosystem services into decision making and policy frameworks for land and soil management (Soil Service, SoilTrEC, and EcoFinders). Defra in the UK has also adopted an ecosystem services approach to inform resource management: the 'ecosystem-based approach' (Beddington, 2010; Defra, 2007, 2013). The UK also released the 'UK National Ecosystem Assessment' (Watson and Albon, 2011), which advertizes new ways of estimating national wealth (Watson and Albon, 2011) and now has a Natural Capital Committee to advise Treasury. In Wales, the new Natural Resources Wales organization incorporates the Environment Agency, Forestry Commission, and Countryside Council for Wales into a single body, to be organized using an ecosystems approach. Thus both policy and the government bodies that monitor and manage the environment are being influenced by the ecosystem services approach.

In this section, recent developments in soil natural capital frameworks that are relevant for agroecosystems are reviewed. The linkages between these frameworks and soils information and soil change are also explored, along with recent progress in ecosystem services frameworks that attempt to synthesize these concepts. Finally, valuation approaches are examined to provide an insight into the different contextual settings where valuation of ecosystem services can be useful.

Agroecosystems and Soil Natural Capital

Soil natural capital is perhaps a more intuitive concept for soil science and agronomy because it focuses on soil stocks, which are routinely measured and inventoried in soil surveys. Soil stocks are the building blocks of the soil infrastructure, so maintaining and developing these stocks is key to delivering ecosystem services. Definitions of soil natural capital and what it includes have developed in recent years. Palm *et al.* (2007) defined soil natural capital as texture, mineralogy, and soil organic matter. Robinson *et al.* (2009) added 'matter, energy, and organization,' recognizing the importance of connections and organization as a stock. Dominati *et al.* (2010a,b) (**Figure 4**) took a more generic approach following Costanza and Daly (1992), defining it as a stock of natural assets yielding a flow of either natural resources or ecosystem services. Dominati *et al.* (2010a,b) (**Figure 4**) differentiated between inherent and manageable soil properties similar to the inherent and dynamic properties used by Robinson *et al.* (2009) (**Figure 5**). These concepts attempt to differentiate between stocks that change through pedological processes and

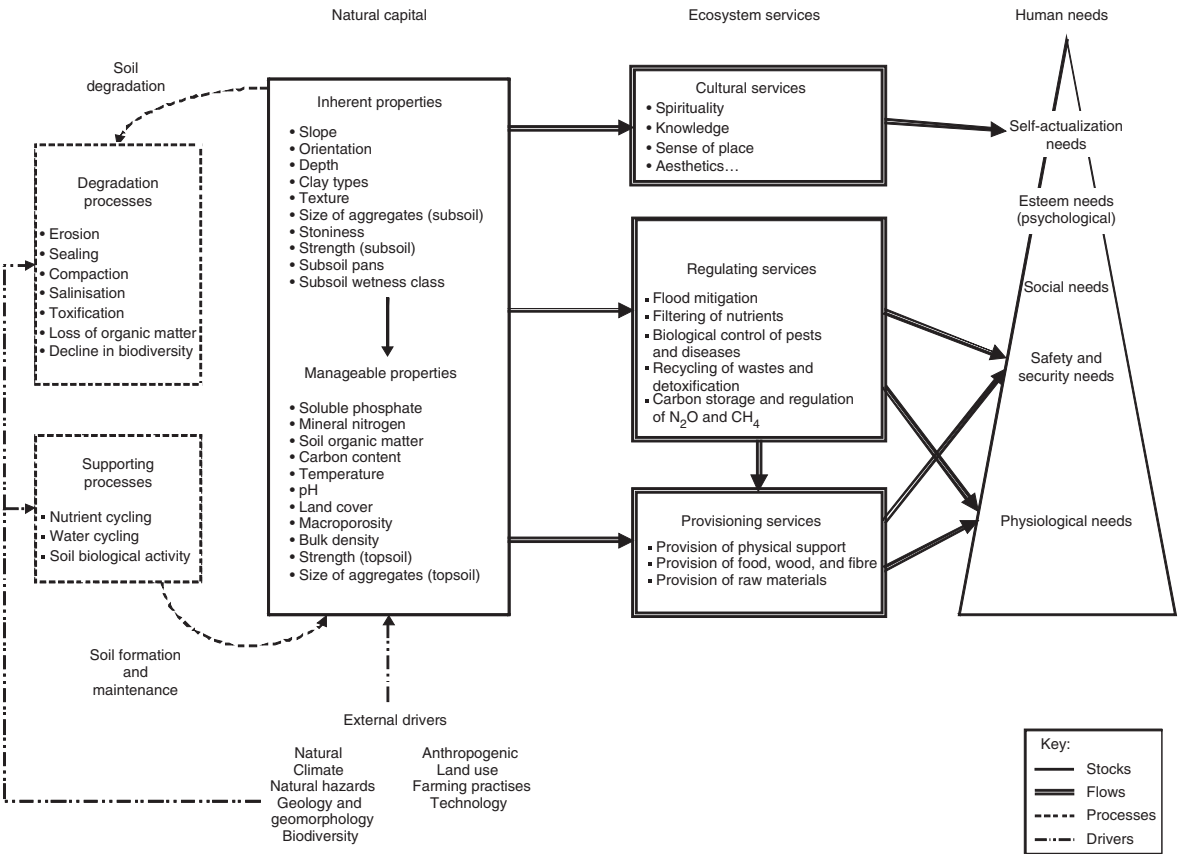

Figure 4 Conceptual framework linking soil natural capital and functioning with ecosystem services provision and human needs. Reproduced from Dominati, E.J., Patterson, M.G., Mackay, A.D., 2010a. A framework for classifying and quantifying the natural capital and ecosystem services of soils. Ecological Economics 69, 1858–1868.

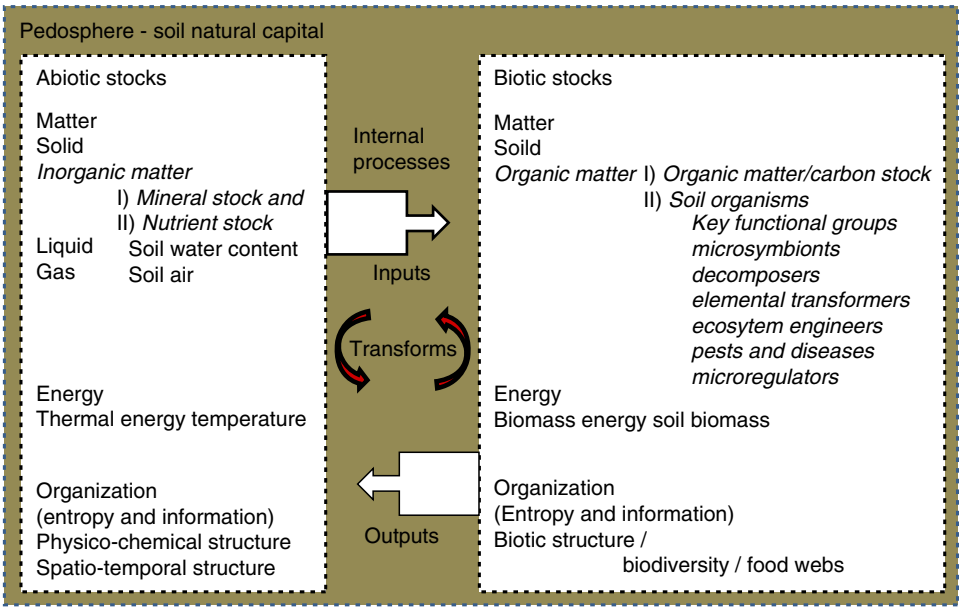

Figure 5 Soil natural capital stocks using a matter, energy, and organization framework (Robinson *et al.*, 2009) divided between abiotic and biotic components (Robinson *et al.*, 2012). Reproduced from Robinson, D.A., Hockley, N., Cooper, D., *et al.*, 2013. Natural capital and ecosystem services, developing an appropriate soils framework as a basis for valuation. Soil Biology and Biochemistry 57, 1023–1033.

those that can be changed by management. For example, inherent soil properties would typically include soil depth, texture, and mineralogy. They cannot readily be changed without significant modification of the soil or its environment (Dominati *et al.*, 2010a,b) (**Figure 4**). Manageable or dynamic soil properties typically include nutrients, organic matter, and soil moisture and structure, all of which can be influenced by land use. Robinson *et al.* (2013) synthesized these concepts, with some of the work done on soil biology (Barrios, 2007) by splitting the capital stocks into abiotic and biotic components (**Figure 5**), in order to recognize that there are constant fluxes and transformations of materials between the biotic and abiotic pools. It is these processes that contribute to soil formation, development or supporting processes in Dominati *et al.* (2010a,b) framework (**Figure 4**). The biological component of soil acts as a biogeochemical cycling engine. Key functional groups rather than particular species are of greatest interest in the delivery of ecosystem services (**Figure 4**).

Farmers understand and appreciate the value of their soil natural capital and continually explore ways to supplement stocks or compensate for a lack of it in different ways. Most commonly, the natural capital is supplemented with added capital or built capital, which is associated with technologies employed to replenish and lift the productive capacity of soils. As an example, fertilizers or animal wastes are used to substitute depleted nutrients and irrigation is used to overcome limited water supplies or water-holding capacity. Artificial drains can be used to improve soil drainage and compensate for a lack of macropores. Identifying where soil natural capital stocks are restricting and how they can be improved using added or built capital is critical for monitoring and the assessment of the sustainability of land uses (Dominati, 2011; Mackay, 2008). An important benefit of using an ecosystem approach with monetized valuation is that changes in stocks can be assessed and interventions valued, allowing the grower the opportunity to consider different options using a comparable value, for example, an economic value.

Agroecosystems and the Provision of Ecosystem Services

The literature addressing the provision of ecosystem services from agroecosystems has focused on two areas: the general provision of ecosystem services from agroecosystems, or more specifically the provision of services from soils. Most of the work done on ecosystem services from agroecosystems uses the MEA (2005) framework (Porter *et al.*, 2009; Sandhu *et al.*, 2010; Swinton *et al.*, 2007; Zhang *et al.*, 2007). The main ecosystem services addressed in relation to agroecosystems are generally the provision of food, feed, fuel, and fiber, the filtering of nutrients and contaminants, carbon storage, greenhouse gases regulation, and pollination and cultural services, including recreation and esthetics. Many of the other ecosystem services provided by agroecosystems (**Table 2**) have not been studied.

General ecosystem service frameworks tend to consign the soil system to 'supporting services' based on the MEA (2005). Although supporting services are vital for the provision of all other services, this classification can result in the role played by soils in the provision of other services being overlooked. For example, the TEEB initiative (TEEB, 2010) has removed supporting services from their framework, as they do not directly benefit society, and now refers to them as 'biophysical structure, processes, and functions' (**Figure 3**). As a consequence one may fail to recognize the large differences that exist between soils in their ability to provide services. For instance, the

Table 2 Goods and ecosystem services provided by agroecosystems and their soils

Service	*Definition*
Provisioning services	
Provision of food, feed, fuel, and fiber	Agroecosystems, first purpose is to produce food and grow crops for a diversity of purposes. Soils physically support plants and supply them with nutrients and water
Provision of raw materials	Soils and vegetation can be a source of raw materials, for example, topsoil, peat, turf, sand, clay minerals, biomedical and medicinal resources, genetic resources, and ornamental resources. However, the renewability of these stocks is sometimes questionable
Provision of support for human infrastructures and animals	Soils represent the physical base on which human infrastructures and animals (e.g., livestock) stand
Regulating services	
Flow regulation	Soils have the capacity to absorb and store water, thereby regulating water flows (fresh water levels) and mitigating flooding
Filtering of nutrients and contaminants	Soils can absorb and retain nutrients (N, P) and contaminants (*Escherichia coli*, pesticides) and avoid their release in water bodies
Carbon storage and greenhouse gases regulation	Soils have the ability to store C and regulate the production of greenhouse gases, such as nitrous oxide and methane
Detoxification and the recycling of wastes	Soils can absorb (physically) or destroy harmful compounds. Soil biota degrades and decomposes dead organic matter thereby recycling wastes
Regulation of pests and diseases populations	By providing habitat to beneficial species, soils and vegetation of agroecosystems can control the proliferation of pests (crops, animals, or humans) and harmful disease vectors (viruses and bacteria) and provide biological control
Pollination	Agroecosystems provided habitat for the regulation of beneficial insect populations, ensuring key biological processes, such as pollination of crops
Cultural services	
Recreation/ecotourism	Natural and managed landscapes can be used for pleasure and relaxation (walking, angling, and mountain biking)
Esthetics	Appreciation of the beauty of natural and managed landscapes (wildlife viewing and scenic driving)
Heritage values	Memories in the landscape from past cultural ties (landscape associated with an important event of regional or national significance)
Spiritual values	Sacred places
Cultural identity/inspiration	Natural and cultivated landscapes provide a sense of cultural identity. This establishes a strong cultural linkage between humans and their environment

The economics of ecosystems and biodiversity: Mainstreaming the economics of nature: A synthesis of the approach, conclusions and recommendations of TEEB. Available at: www.teebweb.org (accessed June 2013); and CICES, 2013. Common International Classification of Ecosystem Services (CICES). Available at: http://www.cices.eu/ (accessed June 2013).

MEA mentions 'soil formation' as a supporting service and recognizes that 'many provisioning services depend on soil fertility' (MEA, 2005, p. 40). Further, the role of soils in the provision of regulating services like flood mitigation, filtering of nutrients, and waste treatment is mentioned, but the part played by soils in the provision of these services and more generally in the provision of services from above-ground ecosystems is not explicitly identified. General ecosystem services frameworks need to be extended to explicitly detail the relationships between soil stocks, soil processes, and soil services, as they contribute to the ecosystem service supply chain.

A major emphasis of ecosystem service frameworks is provisioning services, which include food, feed, fuel, and fiber. The current valuation of agricultural land is primarily based on its productive capacity. This is referred to as Ricardian land value (value in agricultural production) (Daly and Farley, 2010). Other components of land value, such as value for development (location, distance from urban centers, iconic coastal, and lake side, distance to services, such as roads and power lines), land value as a speculative investment, or as a hedge against risk are usually small, but can become significant.

However, soils provide other important functions that support ecosystem services delivery. This was articulated, for example, by Daily (1997), Andrews *et al.* (2004), and Wall *et al.* (2004), who described in detail the services soils provide to human society, from being a substrate for plant growth to buffering floods to recycling wastes. Daily (1997) noted that soils are a valuable asset that 'takes hundreds to hundreds of thousands of years to build and very few to be wasted away' (Daily, 1997, p. 113). Given the important role of soil biology in the functioning of soils, there has been an increasing interest in the contribution of the below-ground biota and microbial communities in supporting processes and thereby providing services (Barrios, 2007; Bell *et al.*, 2005; de Bello *et al.*, 2010; Gianinazzi *et al.*, 2010; Guimarães *et al.*, 2010; Hedlund and Harris, 2012; Keith and Robinson, 2012; Smukler *et al.*, 2010; van Eekeren *et al.*, 2010; Wall *et al.*, 2004; Wall, 2012). Dominati *et al.* (2010a,b) recognized that a

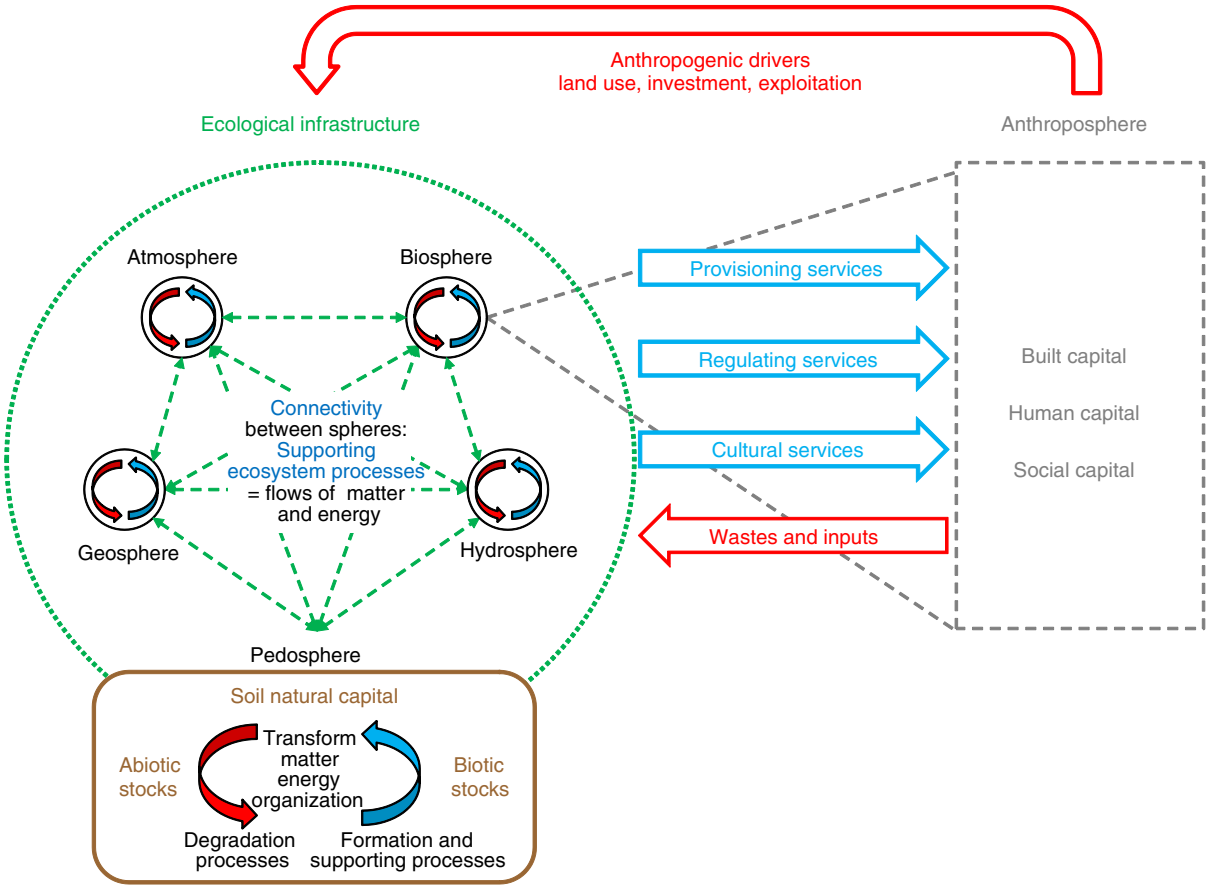

Figure 6 Combined framework for natural capital, ecological infrastructure, and ecosystem services.

combined natural capital and ecosystem service approach is needed for soils (Figure 5). They detailed each of the ecosystem services provided by soils and studied the properties and processes behind them (Dominati, 2011). Robinson *et al.* (2012) also proposed a holistic framework detailing goods and services from soils. Table 2 provides a summary of goods and ecosystem services provided by agroecosystems and their soils based on the latest literature.

Ecological Infrastructure and the Ecosystem Service Supply Chain

No matter how modified they may be, agroecosystems are inseparable from the ecological infrastructure that forms the basis for the provision of ecosystem services. This is because all living organisms require material, energy, and information inputs and produce waste and other outputs.

Recent work has recognized the importance of understanding the continuum along the ecosystem service supply chain (Mooney, 2010; Robinson *et al.*, 2012). Dominati *et al.* (2010a,b) were the first to bring all these concepts together in an overarching framework (Figure 5). In that framework, the ecological infrastructure component is identified on the left side and constitutes the soil natural capital, including the processes acting on and within soils. When put to use, these stocks contribute, along with built capital, toward the delivery of ecosystem services that fulfill human needs. Robinson *et al.* (2012) synthesized these ideas to fit within the stock-flow, fund-service framework used in ecological economics (Daly and Farley, 2010; Farley and Costanza, 2010; Georgescu-Roegen, 1971).

Figure 6 incorporates the concepts developed by Bristow *et al.* (2010), Dominati *et al.* (2010a,b), and Robinson *et al.* (2012) into a framework that goes beyond the pedosphere and considers the bio-, geo-, atmo-, hydro-, and anthropospheres and is applicable to agroecosystems.

On the left-hand side, the earth-system approach (Figure 6) recognizes all the Earth's resources. The major compartments, or 'spheres,' are the atmosphere; hydrosphere, including oceans, surface and ground water, and lakes; the biosphere with its plants and animals, including humans; the pedosphere, the thin skin of soil around the earth; and the geosphere, containing rocks and minerals. The pedosphere is expanded to give an example of the biotic and abiotic stocks that each compartment contains, in this case the soil natural capital stocks (Figure 6). Stocks and their condition within each sphere are tangible materials that can be stock piled and are relatively easy to quantify. The arrows within each sphere represent the processes that build up or degrade stocks. These processes result in the cycling and flow of materials and their transformation. Supporting and degradation processes are

influenced by external drivers, embodied by flows coming from and going to the other spheres. The connectivity among and within spheres, that is the flows of matter, energy, and information, maintain the integrity of the ecological infrastructure, and can also be referred to as supporting processes (Dominati *et al.*, 2010a,b; MEA, 2005; TEEB, 2010).

On the right-hand side of the framework is the anthroposphere. The anthroposphere is contained within the biosphere and includes various types of anthropocentric capital: built capital (transport, communications, water, energy, housing, and other infrastructure), human capital (health, education, and security capital), and social capital (equity, agency, leadership, institutions, and social networks) (**Figure 6**). Ecosystem services, classified here according to the Millennium Ecosystem Assessment typology (MEA, 2005), are the flows coming from the ecological infrastructure, directly useful to humans. Many of these services are intangible, so they cannot be stockpiled and in general can be measured as units per unit time. The processing of goods directly harvested from the various spheres, as well as the use of natural stocks, built capital and ecosystem services, results in wastes, or impacts on each of the earth system spheres. Anthropogenic drivers, such as land use and management, determine the levels of natural resource exploitation, changes to natural capital stocks and the provision of ecosystem services, and the nature, and quantity of wastes produced.

A sustained flow of ecosystem services depends on the integrity, and thus connectivity, of the ecological infrastructure. This means that the entire supply chain needs to be considered when identifying and determining the impacts of land management on agroecosystems. At present, the value of an agroecosystem is generally limited to its immediate economic productivity capacity, but agroecosystems provide a wide range of services, and are also valuable for maintaining the integrity of ecological infrastructure.

The ecosystem services approach has been very useful in highlighting the lack of consideration for the holistic and long-term value of agroecosystems. An important challenge is how best to deal with recognizing the value of the ecological infrastructure, along with the ecosystem services, beyond provisioning. Given the global level of environmental degradation, food security for growing populations can only be achieved via agroecosystems that serve a dual purpose. Along with producing socioeconomic goods, such as food, feed, fuel, and fiber, the farming enterprises must also contribute toward the integrity of the ecological infrastructure that underpins the continued provision of essential ecosystem services (Gliessman, 2007).

Approaches to Valuation

The economic value of commodities produced by agroecosystems is well understood. Agricultural products are gradually transformed as they progress along the 'production chain,' where economic value is often added at a number of stages. Agroecosystems are also closely linked to the economic value of land. The value of agricultural land is currently defined mostly by its productive capacity. The productive capacity of the land, plus its location, plus the value of the built infrastructure on the land determine the land's economic value. There are very few valuation systems that recognize or capture the other contributions land makes to the well-being beyond its economic contribution. To achieve land use sustainability, one needs to value the multifunctionality of this scarce resource and include it in decision making.

To convince financial institutes, economists, and others in society regarding the value of soils, the current approach to valuing land and agroecosystems needs to be extended to include all the ecosystem services provided. Approaches that have the capacity to quantify and value the ecosystem services supplied by agroecosystems would be a significant advance on the current method. Such approaches would provide a holistic representation of the sustainability of current land use, and the pivotal role the pedosphere plays in human well-being.

It has been widely argued that the undervaluation of the contributions of ecosystems to human welfare, including agroecosystems, can be partly explained by the fact that they are not adequately quantified in terms comparable with economic services and built capital (Braat and de Groot, 2012; Costanza *et al.*, 1997). In response, since the 1990s, an increasing number of studies have focused on the economic valuation of ecosystem services (Costanza *et al.*, 1997) including services from agroecosystems (Breure *et al.*, 2012; Porter *et al.*, 2009; Sandhu *et al.*, 2008). This is because framing ecological concern in economic terms has great appeal to decision makers (NZIER, 2013; Braat and de Groot, 2012; Robinson *et al.*, 2012).

There is an enormous scope to improve the provision of ecosystem services from agroecosystems, but first a more holistic value of land is needed to inform a number of contexts. Economic valuation of ecosystem services from agroecosystems can assist in (Defra, 2007; OECD, 2002):

- revising national accounting: fully accounting for the environmental impacts of economic activities in decision making, use indicators of change in natural capital stocks, contribution of agriculture to GDP/exports,
- land use decision making: priority setting, cost effectiveness of policy, comparing infrastructure developments/land uses/policy options using cost–benefit analysis including ecosystem services provision and costs of degradation,
- creating new insights for policy development,
- designing incentives, setting charges/taxes, creating markets for ecosystem services (policy around payments for ecosystem services), and
- communicating with the public and land managers about the value (e.g., moral, esthetic, economic, and ecological) of the environment and agroecosystems.

Value is often solely associated with price. Although price is a type of value (monetary value), the two are not synonymous, and any kind of commodity, including ecosystem services, can have many values associated with it. Valuation is about using a common measure to bring things into a frame of comparability (Robertson, 2012), and the common measure might or might not be of economic value.

Environmental management is, as a rule, associated with qualitative information in valuation problems. Thus, there is a clear need for methods that are able to take into account qualitative information, or information of a 'mixed' type (both qualitative and quantitative) (Munda *et al.*, 1994). Martinez-Alier *et al.* (1998) argued that incommensurability (the

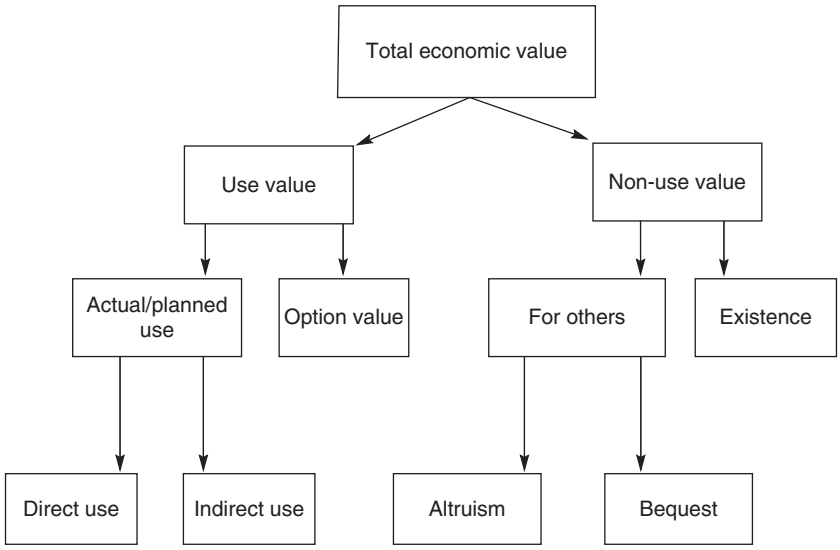

Figure 7 Total economic value. Adapted from Defra, 2007. An Introductory Guide to Valuing Ecosystem Services. London: Department for Environment, Food and Rural Affairs.

absence of a common unit of measurement across plural values) is the 'foundation stone for ecological economics' (Martinez-Alier *et al.*, 1998, p. 279), and that instead of complying with any type of physical reductionism (monetary, energy, or other), valuation should push toward multicriteria analysis and the use of weak comparability (comparing options without recourse to a single type of value) and which does not imply a hierarchy of values. Ecological economics investigates a range of theories of value including the neoclassical economic theory of value. These include:

- The embodied energy theory of value (EMERGY) (Hannon *et al.*, 1986; Patterson, 1998): EMERGY considers energy as the fundamental driver of ecological systems and thereby the economy.
- Ecological value: Ecological value is defined as the value of direct and indirect interactions of a component of an ecosystem, an ecological entity (species), or compartment, with the other components of the same ecosystem (Cordell *et al.*, 2005).
- Contributory value: Natural ecosystems make contributions to the value of final economic goods and services (Norton, 1986; Ulanowicz, 1991). Contributory value assigns value to environmental resources not due to their direct value to humans, but according to their indirect role in maintaining and accentuating the ecosystem processes that support these direct benefits (Costanza *et al.*, 1989, p. 338).

Even though a range of value theories exist, economic value is still getting the most traction in resource management. The rationale of neoclassical economic valuation of ecosystem services lies in the need to ensure that all the services are taken into account in decision making on the same basis as the conventional costs and benefit of conventional economic activity (Pearce and Barbier, 2000).

Neoclassical economics uses the concept of total economic value (TEV). TEV can be broken down into several components, which can then be used to describe the value of ecosystems (**Figure 7**). TEV can be broken down into use and nonuse values (Defra, 2007; Patterson, 1999; Pearce, 1995). Use values include direct and indirect use, and option values:

- Direct-use value: The value of all goods and services derived from the direct or planned use of ecosystems, consumptive use of resources (e.g., food, timber, and parks), or nonconsumptive use of services (e.g., recreation and landscape amenity). They are generally attributed to provisioning and cultural services.
- Indirect-use value: They are derived from the functioning of ecosystems underlying direct-use activities (Defra, 2007; Pearce, 1995). Indirect-use values correspond to supporting processes and regulating services.
- Option value: The value that people place on having the option to use, directly or indirectly, a resource or service in the future, even if not currently in use (Costanza *et al.*, 1989; Defra, 2007).

Nonuse value, also referred to as 'passive value,' is not related to the actual use of ecosystem goods and services, but is derived from the knowledge that ecosystems are maintained (Defra, 2007). They concern all types of services. Nonuse value can be further subdivided into three main components (**Figure 7**):

- Existence value: It relates to the existence of ecosystem goods and services even if an individual has no actual or planned use for it (Costanza *et al.*, 1989). Many people are willing to pay for the preservation of species (whales and rainforest insects) even if they know they might actually never be in contact with them.
- Altruistic value: The value individuals attach to the availability of the ecosystem resources or services to others in the current generation.
- Bequest value: The value that people place on knowing that ecosystem goods and services will be available for future

generations. Bequest value is sometimes regarded as part of existence value.

Some authors (e.g., Pearce, 1995) debate the merit, and hence application of this classification to neoclassical economic valuation, but the TEV framework is a useful tool to identify what type of value is being measured, based on the type of good or service concerned, thereby assisting the selection of an appropriate valuation method (Defra, 2007).

Neoclassical economic valuation is used to measure public and individual preferences for changes in ecosystem services provision. **Table 3** presents a number of valuation techniques currently used for the valuation of ecosystem services. Valuation techniques for valuing ecosystem services can be distinguished by the type of preferences they elicit: (1) revealed or (2) stated.

1. Revealed preference techniques obtain values by looking at individuals' preferences and willingness to pay (WTP) for a marketable good with environmental attributes. These techniques rely on conventional markets, actual markets in which the environmental goods and services are already traded (e.g., timber market or CO_2 market). Revealed preference techniques can also value nontradable goods and services indirectly through marketed goods and services that embody their values (e.g., air pollution affects the price of houses) (**Table 3**).
2. Stated preference techniques elicit individuals' preferences for a given change in a natural resource or service through structured questionnaires (Defra, 2007; Pearce and Barbier, 2000). Stated preference techniques use hypothetical markets, which are simulated markets, where individuals can express their WTP for a nontraded environmental good or service (Pearce and Turner, 1990; Pearce and Barbier, 2000). These techniques, including contingent valuation, choice modeling, and the more modern deliberative group valuation, are the only ones that can estimate nonuse values for some natural resources. In some cases, these nonuse values can be a significant component of the overall TEV (Defra, 2007, **Table 3**).

Valuing environmental goods and services provides additional information that can potentially be used in a benefit–cost analysis (BCA), if appropriate. BCA quantifies, in monetary terms, as many of the costs and benefits of a proposal as is feasible (Defra, 2007). It has been, and still is, extensively used for resource management and decision making. Failure to include ecosystem services in benefit–cost calculations implicitly assigns them a value of zero. To date this has been the norm, and it has contributed to the major depletion of natural capital stocks and increasing environmental issues (MEA, 2005). Valuing ecosystem goods and services for inclusion in BCA is one of the tools available to advance sustainable development by ensuring that policies completely account for the costs and benefits of development proposals on the natural environment (Defra, 2007). For policy making in the context of agroecosystems and resource management, the more relevant application of economic valuation is to compare management options, or assess an investment in either built (e.g., irrigation) or ecological (e.g., soil conservation) infrastructure.

A number of problems have been raised regarding the use and effectiveness of neoclassical economic valuation in assessing the value of ecosystem goods and services that, as yet, lack markets, and in taking these values into account in decision making. These include:

1. Imperfect knowledge or information: Some neoclassical valuation techniques that try to elicit individual's WTP for a nonmarket good are confronted by anomalies based on human beings having imperfect knowledge of ecological processes and functions (Patterson, 1998). This is particularly important when valuing ecosystem services as they are often abstract and the result of complex biophysical processes unknown to nonexperts. Even when using revealed preference methods, challenges arise from the complexity of the biophysical processes. Imperfect information about processes and the provision of ecosystem services is transferred to the quantification of the service and then the economic valuation. Data availability is also always a challenge because a great deal of information, both biophysical and economic, is needed for the quantification and valuation of ecosystem services.
2. Discounting: Another argument against neoclassical economic valuation is its nonequitable aspect when it comes to the intergenerational assignment of benefits and costs. Discounting is an important, but very controversial part of BCA. It is used to compare present and future costs/benefits (Gasparatos *et al.*, 2008). The greater the discount rate adopted, the greater the devaluation of future costs/benefits. Therefore, in projects with a long time horizon, for example, encompassing several generations, future impacts can count for little, or even nothing. This is contrary to the interests of future generations, because it amounts to a nonequitable distribution of costs and benefits. It has been suggested that low discount rates should be adopted for projects that will greatly affect future generations, since small discount rates capture long-term net benefits, whereas higher discount rates put more weight on short-term benefits.
3. Market failure: The exchange of some economic goods and services takes place in markets. However, markets can, and often do, fail. One of the most common areas of market failure is in the provision of public goods, such as ecosystem services. Either ecosystem services are lacking markets, or if markets exist, they can fail to reflect the entire value of the service. For example, there is a market for carbon. The multifunctional value associated with soil carbon includes not only carbon storage, but also the importance of organic matter for soil structure cohesion, and nutrient retention. These values are always very significant for soil functioning, whereas carbon prices fluctuate quickly and frequently. The use of stated-preference methods to determine the value of ecosystem services offers solutions to deal with market failure.
4. Validity of techniques: Whatever the technique used, there are always uncertainties associated with it. For example, where cost-based approaches are used to value services, sometimes the valuation is limited to the scale covered by the technique or the infrastructure element considered, for example, dam, road, or building, whereas the extent of the

Table 3 Economic valuation methods

Market type	*Method name*	*Method type*	*Type of value captured*	*Definition*	*Example*
Conventional market	Market price	Revealed preferences	Use values	Market prices can be used directly to capture the value of ecosystem goods and services already traded in markets	Market price of food, wood, or agricultural land
	Productivity change	Revealed preferences	Use values	Productivity change approach is not a valuation technique per se but can be used with diverse valuation techniques. It uses production functions to describe the relationship between a particular ecosystem service, the natural capital stocks behind it, and the production of a market good	Production function linking soil type, irrigation quantity, and air temperature to wheat yield (the traded commodity)
	Defensive expenditure	Revealed preferences	Use values	Defensive expenditure focuses on the price paid by individuals to mitigate against environmental impacts. The method uses the money spent by individuals to avoid exposure to degradation of the environment and a decrease in the provision of an ecosystem service as a proxy for the value of the service	The cost of mitigation techniques on farm to prevent nutrient and contaminant loss are used as a proxy for the value of the filtering of nutrients
	Replacement cost	Revealed preferences	Use values	The replacement cost approach uses the costs of replacing or restoring damaged ecosystem goods or services to their original state or productivity, using market goods, as a proxy for the value of the service	Cost of plowing to improve soil porosity as a proxy for the value of support, cost of drainage
	Provision cost	Revealed preferences	Use values	The provision cost approach is a variant of the replacement cost. It does not refer to the replacement or restoration of the ecosystem service *in situ*, but to actual costs of providing the damaged service through alternative means. This technique relies on the existence of human-made systems and techniques	Wetlands that provide flood protection may be valued through the cost of building human-made defences of equal function, e.g., dams or flood banks
	Hedonic pricing	Revealed preferences	Use values	Hedonic pricing seeks to find a relationship between environmental characteristics (view levels and air quality) and the price of properties (house and farm land). The value of the environmental component (good or service) can therefore be captured by modeling the impact of all possible factors influencing the price of the property	Influence of soil properties on farmland values
	Travel cost	Revealed preferences	Use values	The travel cost method is predominantly used in outdoor recreation modeling (fishing, hunting, boating, and forest visits). It is a survey-based technique that uses the cost of a trip taken by an individual to a recreation site (e.g., travel costs and entry fees) as a proxy for the value of the recreational service	Travel costs and entry fees are used as a proxy for the recreational value of, for example, a national park

(*Continued*)

Table 3 Continued

Market type	*Method name*	*Method type*	*Type of value captured*	*Definition*	*Example*
Hypothetical market	Contingent valuation	Stated preferences	Use and nonuse values	The contingent valuation method aims at obtaining an estimate of the economic value of a marginal change in the level of provision of an ecosystem good or service not traded in market by directly questioning a sample of the population concerned	Contingent valuation method uses questionnaires to obtain estimates of the social benefit from soil erosion reductions from programs to mitigate the off-site impacts of soil erosion for a watershed. Ask respondents their willingness to pay (WTP) for different scenarios to change erosion levels more than 20 years. Bids can be expressed as tax payments and used to suggest upper limits on per haectare payments for soil conservation programes (Colombo *et al.*, 2006)
	Choice modeling	Stated preferences	Use and nonuse values	Choice modeling is a family of survey-based methodologies for modeling preferences for goods, where goods are described in terms of their attributes and of the levels that these attributes take. Respondents are presented with several alternative descriptions of a good, differentiated by their attributes and levels, and are asked to rank the various alternatives, to rate them or to choose their most preferred. One of the attributes of the good is the price/cost, which is used to indirectly record people's WTP from their rankings, ratings, or choices	A lake may be described in terms of water quality, water clarity, number of fish species, catches per year, and entry fees. Participants are presented with different combinations of attributes and asked to choose their preferred combination or rank the alternative combinations. The results are then used to value an extra unit of, for example, water quality
	Group valuation	Stated preferences	Use values	Group valuation methods are based on principles of deliberative democracy and the assumption that decision making about public goods, such as ecosystem services, should not result from the aggregation of separately measured individual preferences, but from open public debate	Focus groups: aim to discover the positions of participants regarding an issue. In-depth groups: similar to focus groups, but less closely facilitated, and focus on how the group creates discourse on the topic. Citizens' juries: A sample of citizens considers evidence from experts and other stakeholders, hold group discussion on the issue, and give an informed opinion that is supposed to reflect public opinion. Deliberative forums: they spend time listening to the opinions of others (experts, stakeholders, or general public) with the aim of forming a collective view

service can be greater. In such a case, the price obtained will not be representative of the real value of the service. With stated preferences like contingent valuation or choice modeling, many biases, such as design bias, cognitive burden, strategic bias, or information bias are common when respondents state their WTP (Pearce *et al.*, 2006).

5. Sustainability concerns, such as rights, fairness, and intergenerational equity (Spash, 2007).

Because of the problems associated with economic valuation of ecosystem services, researchers are increasingly using several techniques simultaneously to compare results. Cost–benefit analysis is still frequently used because it is cheaper and quicker than other methods, and is well understood by decision makers. But methods, such as deliberative monetary valuation, a novel hybrid of economic and political processes to value environmental change, are now being used more often. This is because they are based on deliberative processes between stakeholder groups and therefore offer some answers concerning fairness and equity.

Application of the Concepts to Resource Management

Challenges of the Ecosystems Approach for Resource Management

Generally speaking, the ecosystems approach and the concepts of natural capital, ecological infrastructure, and ecosystem services are powerful tools for resource management as they contribute to a better understanding of the linkages between on-site changes and off-site impacts. With respect to agroecosystems and soil in particular, these concepts provide a holistic framework, which places agroecosystems within the greater ecological infrastructure.

A number of challenges must be overcome if the ecosystem services approach is to be used as an overarching framework for the management of agroecosystems. Robinson *et al.* (2012) identified four key research areas needing attention to further develop the soils' component of the ecosystems approach. Combining these specific research priorities for soils with general guidelines for application of the ecosystems approach (Braat and de Groot, 2012; Omuto *et al.*, 2012; TEEB, 2010) identifies the key challenges as:

- Framework development, to identify exactly how, where, and when soils and the other spheres are involved in the provision of ecosystem services.
- Quantifying changes to the natural capital stocks under the impact of natural and anthropogenic drivers. This can be achieved through monitoring and modeling of stocks, fluxes, and transformations, within and between spheres and identifying appropriate indicators that can be used in monitoring schemes. This requires enhancing the quantity and quality of information on the functioning of ecological infrastructure: data generation and collection, analysis, validation, reporting, monitoring, and integration with other disciplines.
- Better assessment of spatial and temporal dynamics of service provision, including threshold changes, alternative states, and irreversibilities, especially in relation to beneficiaries.
- Developing means to value ecosystem services and incorporating these values into decision making about alternative management options.
- Developing management strategies and decision-support tools including models and maps of natural resources.
- In the long-term harmonization of methods, measurements, and indicators for the sustainable management and protection of soil resources.

Investing in Ecological Infrastructure for Resource Management

The concept of ecological infrastructure provides a framework that locates ecosystem services within a holistic model of nature. Ecological infrastructure is also directly comparable to built infrastructure in terms of the need for public investment to maintain its integrity. In developing and developed countries alike, there are increasing demands for additional and improved public infrastructure. The global recognition of the need for built infrastructure investment can be used to exemplify and prioritize investment in ecological infrastructure.

Bristow *et al.* (2010) argued that although built infrastructure investment has been ever-increasing, one has not been investing sufficiently in the ecological infrastructure. Indeed, inadequate investment in ecological infrastructure has led to a worsening environmental crisis, in which critical ecosystem services have been and are being lost across the globe. For example, 60% of ecosystem services examined by the Millennium Ecosystem Assessment (MEA, 2005) was found to be degraded. This means that the underlying ecological infrastructure that provides these services is deteriorating, or has collapsed. When the current state of global ecological infrastructure is added to increasing population growth and resource consumption trends, the need for significant and ongoing investment in ecological infrastructure is undeniable.

Investing in ecological infrastructure involves three strategies that must be carried out concurrently:

1. Research and extension investment to improve and disseminate knowledge about ecological infrastructure and the ecosystem services it provides;
2. Restoration of degraded ecological infrastructure; and
3. Maintenance and enhancement of the capacity of relatively undisturbed ecological infrastructure to continue to produce ecosystem services.

Improving our knowledge about ecological infrastructure is necessary to ensure that 'returns' on ecological infrastructure investments are maximized. Although there are still many knowledge gaps, humans already possess a vast amount of information about how healthy catchments, forests, rivers, wetlands, soils, and coral reefs should look and function. The extent and depth of this knowledge is sufficient to begin investing in restoring, maintaining, and enhancing ecological infrastructure immediately (Karr, 1993; MEA, 2005). Sufficient investment in ecological infrastructure also obviates the various problems that arise from the use of neoclassical economic concepts to value ecosystem goods and services that are not amenable to market-based logics. Whether or not ecosystem

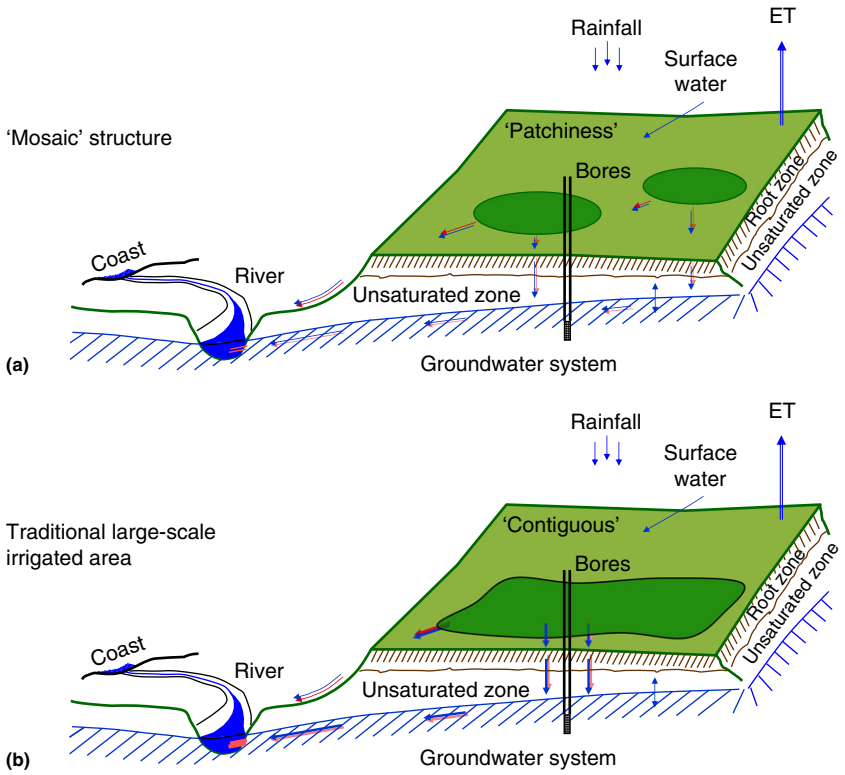

Figure 8 Schematic showing the basic features of irrigation mosaics compared to large contiguous irrigation developments. Reproduced from Paydar, Z., Cook, F.J., Xevi, E., Bristow, K.L., 2007. Review of the current understanding of irrigation mosaics. CRC for Irrigation Futures Technical Report No. 08/07. CSIRO Science Report 40/07. Available at: http://www.irrigationfutures.org.au/imagesDB/news/CRCIF-TR0807-web.pdf (accessed 06.01.10).

processes and functions are able to be traded in markets, if the integrity of the ecological infrastructure that produces ecosystem services is maintained, the services will continue to flow.

A key operational aspect of investing in ecological infrastructure is the development of newly built infrastructure and the reconfiguration of existing built infrastructure, so that these contribute toward ecological integrity. This is particularly important in the case of agroecosystems. One approach that can be used for both new and existing irrigation developments is based on the concept of mosaics (Figure 8). This approach, which involves developing smaller discrete patches of irrigated land dispersed across the landscape, may offer an alternative to large-scale contiguous irrigation systems (Paydar *et al.*, 2007). Zones of transition between adjacent ecological systems are important characteristics of natural mosaics and play a key role in energy and material fluxes (Paydar *et al.*, 2007). Irrigation mosaics could be used to create or enhance zones of transition in the agricultural landscape, leading to greater biodiversity and improved microclimates. Improved zones of transition also help to minimize erosion and absorb surplus nutrients, sediments, and solutes that flow from the surrounding crop fields, thus decreasing the discharge of irrigation 'waste' out of the irrigation area (Paydar *et al.*, 2007). Understanding the likely performance of irrigation mosaics can also help to identify how existing irrigation systems could be reconfigured for improved harmonization with natural systems (Figure 8) (Story *et al.*, 2008).

To sum up, one cannot escape the reality of a finite planet with limited resources, growing human populations, and increasing demands for ecosystem services. Unless the approaches to NRM include programs for restoring, maintaining, and enhancing ecological infrastructure, the world's ecosystems, including the agroecosystems, will continue to be fragmented and destroyed.

Use for Policy Making at the Regional Scale

In developed countries around the world, government bodies responsible for NRM are increasingly under pressure from the general public to deliver higher environmental standards when managing land for sustained use of resources. For example, in New Zealand over the past 50+ years, investment in soil conservation in agroecosystems has run into billions of dollars. Soil conservation policies aim to reduce the risk of soil erosion in vulnerable land (e.g., hill and steepland country), the downstream costs associated with nutrient losses and sediment loadings to waterways, and damage to productive farmland and towns. Current evaluation of soil conservation policy and justification for the associated expenditure is limited to an assessment of the reduction in the loss of productive capacity, soil loss, and sediment and downstream impacts on community of flooding and sedimentation. Until the full range of ecosystem services below and above ground is considered in the analysis, the true cost of erosion, beyond productivity loss, and full value of soil conservation is not available for informed land-use decision making.

In the case of soil conservation, an ecosystem services approach offers a methodology that can answer such questions, through the following steps:

- Quantify the provision of ecosystem services from the agroecosystems of interest (e.g., hill country sheep and beef farming) to assess the baseline flows of ecosystem services under current land use on uneroded soil, before implementation of a soil conservation programe, based on information from existing planning tools.
- Compare these baseline flows with an assessment of the provision of ecosystem services from a similar agroecosystem with well-developed soil conservation plan and practices, for example, wide-spaced poplars on steep hill for sheep and beef pastures, to see how the soil conservation policy impacts the provision of ecosystem services.
- Use the quantitative information for both systems in an economic valuation of the provision of ecosystem services from the two base-line scenarios.
- Quantify and value the provision of ecosystem services from eroded land to evaluate the loss of services compared to an undisturbed pedosphere and ecological infrastructure.
- Characterize and quantify the recovery profile of the provision of ecosystem services in the years following an erosion event (0–1000s years) based on soil recovery data to assess how the provision of ecosystem services recovers.
- Implement a cost–benefit analysis of investment in soil conservation on steep hill pasture prone to erosion compared with no conservation, using an ecosystems services approach, to assess the return on investment from the soil-conservation policy.
- Inform the 'full value of the soil-conservation policy,' enabling a more holistic assessment of flood and catchment management, by allowing, for example, a comparison of the value of a dollar spent on conservation practices (e.g., tree planting) with engineers' structures, such as stop banks.

Such studies address actual conservation issues and show how an ecosystem services approach can be used to advance existing governance frameworks to solve resource management challenges. Understanding how current investments in built capital and current and future investments in ecological infrastructure are likely to change the flow of ecosystem services from managed landscapes is critical to assess the efficiency, cost effectiveness, and sustainability of resource management policies, and for a more complete understanding of the socialecological value of our land.

Conclusion

The ecosystem services approach to NRM is undoubtedly an increasingly influential tool, which is very useful to highlight the holistic and long-term value of agroecosystems. Challenges remain for its implementation. Future NRM needs to focus concurrently on:

- Addressing dual purpose served by agroecosystems: producing socioeconomic goods, as well as underpinning the continued provision of essential ecosystem services.
- Restoring, maintaining, and enhancing the capacity of current ecological infrastructure to continue providing ecosystem services.
- If and when economic valuation of environmental change is needed, increasingly using valuation techniques that answer concerns about fairness and equity.
- Providing solutions based on sound science to minimize potential damage, on top of looking for solutions to overcome limitations.

The ecosystem services approach to NRM has a tremendous potential to help achieve goals, such as Green Growth and the sustainable use of finite natural resources, while enabling agroecosystems to be adaptable and more resilient to uncertainty, change, and shocks.

Organic Agricultural Production: Plants

JM Wachter and JP Reganold, Washington State University, Pullman, WA, USA

© 2014 Elsevier Inc. All rights reserved.

Glossary

Agroecosystem An agricultural system of interacting biological communities and environmental components.
Biodiversity The diversity of species and functional groups in a natural or agricultural ecosystem.
Compost Decomposed organic materials such as plant and animal matter, usually prepared in a controlled manner via mixing and aerating.
Conventional agriculture Typically chemical-intensive, short-rotation cropping systems designed for maximum yields, which rely on synthetic chemical inputs to control pests and maintain soil fertility.
Cover crop A nonharvested crop grown for the purpose of preventing soil loss, adding organic matter, fixing nitrogen (in the case of leguminous cover crops), or otherwise improving soil quality and health.
Crop rotation A planned sequence of a diversity of crops grown in succession over multiple years in the same field.
DDT A synthetic insecticide introduced in the 1940s, known technically as dichloro-diphenyl-trichloroethane.
Green manure A nonharvested crop grown for the purpose of adding organic matter, fixing nitrogen (in the case of leguminous cover crops), or otherwise improving soil quality and health.
Nutrients Elements that are necessary for organisms to live, including nitrogen, potassium, phosphorous, and a variety of other nutrients that are required only in very small quantities.
Organic farming The practice of farming that generally avoids the use of synthetic fertilizers, pesticides, and herbicides, and instead relies on biological interactions for agricultural functions.
Organic nutrients Nutrients that are in the form of organic matter or organic compounds.
Soil organic matter Refers to the living or dead plant and animal material in the soil, including crop residues, animal manure, microorganisms, and any other biological material in various stages of decomposition.
Soil quality The capacity of a soil to sustain biological activity, maintain environmental quality, and promote plant and animal health.
Sustainable agriculture For a farm to be sustainable, it must produce adequate amounts of high-quality food, conserve resources, and be environmentally safe, profitable, and socially responsible.
Synergy The condition of two or more interacting components resulting in a greater effect than any/either individual component alone.

Introduction

Sale of organic foods in the past two decades has been one of the fastest growing market segments within the global food industry (Willer *et al.*, 2009). As a result, more arable land, research funding, and research test sites are being devoted to organic farming worldwide. In addition, there has been an increase in published scientific studies of organic systems, with different types of studies evolving and more parameters being measured.

Organic farming systems have been shown to be energy-efficient, environmentally sound, productive, stable, and tending toward long-term sustainability (Lotter, 2003; Mäder *et al.*, 2002). Organic farming systems do not represent a return to the past. They use modern equipment, certified seed, soil and water conservation practices, improved crop varieties, and the latest innovations in feeding and handling livestock. Organic farming systems range from strict closed cycle systems that go beyond organic certification guidelines by limiting external inputs as much as possible, to more standard systems that simply follow organic certification guidelines.

Organic farming relies on the integration of a diversity of farm components, the cycling of nutrients and other resources, and stewardship of soil and environment. The result is a farming system that is more knowledge intensive than resource intensive. By minimizing or eliminating chemical inputs such as artificial fertilizers, synthetic pesticides, and antibiotics, and instead using composts and manures, organic farms aim to build soil, minimize pollution, and recycle nutrients.

This article aims to describe organic agriculture in its variety of forms. Organic agriculture is at once a set of ideological principles and a science-based agronomic practice. It is a

quickly expanding global market force as well as an alternative to conventional agriculture that seeks socioeconomic and environmental sustainability on local and global scales. This article discusses the global history of the organic movement and its international origins, the role of organic certification, global trends in sales and production of organic foods, the underlying principles of organic farming, examples of management practices, and current research on the production, economic, environmental, and social sustainability of organic farming.

History

Before the advent of chemical pesticides and synthetic fertilizers, farmers had to rely on organic materials for fertilizers and on physical methods of weed control. However, these historical farming systems were often unrelated to the organic farming practices of today. Often these historical farming systems relied on depleting the natural soil resources by not replacing harvested nutrients, not protecting the soil from erosion, and not sufficiently rotating crops. Organic farming is not a reversion to past practices, but rather, it is what Vogt (2007: p. 12) calls "an intensification of farming by biological and ecological means in contrast to chemical intensification by mineral fertilizers and synthetic pesticides."

Around the turn of the twentieth century, agriculture was quickly changing, with increased mechanization, the discovery of inorganic mineral fertilizers, and shipping of crops over larger distances (Conford, 2001). These rapid changes began to cause problems with soil compaction, uncontrollable pest and disease outbreaks, soil acidification, and declines in soil fertility. Additionally, the increasingly urban populations of many developed countries at the time led to changes in lifestyle and diet. Concern over these problems set the stage for organic agriculture movements to develop independently in Central and Western Europe, the US, and Japan.

In Germany, the early 1900s saw the rise of the life reform movement in reaction to increasingly unhealthy urban lifestyles and diets. The life reform movement sought a natural way of living, which consisted of leading a physically active agrarian-based life and a strictly vegetarian diet of locally and naturally produced food. Leaders of the movement encouraged composting, green manures, conservation tillage, and recycling municipal wastes on fields to replace lost nutrients. They saw the use of synthetic fertilizers as the cause for decreasing food quality. The Natural Farming and Back-to-the-Land Association was founded in 1927 and established early standards for organic farming, which were published in journals and through lectures and courses. Ewald Könemann's three-volume book entitled Biological Soil Culture and Manure Economy is an important culmination of the principles of the natural farming movement that was emerging from Germany (Vogt, 2007).

Complementing the life reform movement, in 1924 in Koberwitz, Germany (now Kobierzyce, Poland), an Austrian scientist Rudolph Steiner gave a series of eight lectures on agriculture later published under the title Spiritual Foundations for the Renewal of Agriculture (Paull, 2011). Founder of the Anthroposophy spiritual movement and the Waldorf educational philosophy, Steiner's agricultural lectures offered guidelines for organic farming practices, stressing the ideas of the farm as an organism, of on-farm nutrient cycling, and of the close integration of the various parts (or 'organs') of the farm (Vogt, 2007). A mix of scientific and astrological thinking, Steiner's lectures also laid the groundwork for biodynamic agriculture, popularized by Ehrenfried Pfeiffer's (1938) publication of Bio-Dynamic Farming and Gardening (Pfeiffer, 1938). In 1928, the first standards for biodynamically grown food were developed under the name Demeter, which is thought to be the first set of agricultural food standards (Schmid, 2007; Gomiero *et al.*, 2011).

In the early 1900s, a handful of American and British agricultural scientists also began to draw contrasts between their countries' increasingly industrialized farming and the farming practices that they observed in parts of Asia. Former Chief of the Division of Soil Management for the United States Department of Agriculture (USDA), Franklin H. King, left America in 1907 to study the farming practices of East Asia. He published his observations in a 1911 book entitled Farmers for Forty Centuries, in which he described the many lessons he thought American and European agriculturalists should learn from Chinese, Korean, and Japanese farmers, specifically their practices of composting and returning all waste products to farmland and their long-term view of maintaining and building soils with cover crops and organic amendments (King, 1911). "Man," King wrote, "is the most extravagant accelerator of waste the world has ever endured. His withering blight has fallen upon every living thing within his reach, himself not excepted; and his besom of destruction in the uncontrolled hands of a generation has swept into the sea soil-fertility which only centuries of life could accumulate – fertility which is the substratum of all that is living" (King, 1911: pp. 196–197).

During the same period, Sir Robert McCarrison, a British nutritionist, began remarking on the linkages between the excellent physical health, whole food diets, and healthy integrated farming systems of three tribes in India. Returning to England in 1935, he greatly influenced agricultural and health professionals, and inspired physician G.T. Wrench to write his book entitled The Wheel of Health (Wrench, 1938).

Often cited as the father of modern organic agriculture, Sir Albert Howard first traveled to India in 1905, and it was not until 1924 that he was given the bureaucratic freedom and leeway to pursue integrated interdisciplinary agricultural research in the state of Indore. Familiar with King's writings on composting and soil building, Howard adapted these practices to the local conditions of Indore, resulting in what became known as the Indore Process. Howard's (1931) book entitled The Waste Products of Agriculture quickly spread the concepts of the Indore composting process around the world (Howard, 1931). Just as McCarrison attributed a person's health and resistance to disease to their appropriate diet, activities, and surroundings, Howard saw healthy soils as the foundation for healthy plants and animals (Conford, 2001). In 1940, Howard wrote his most famous work, An Agricultural Testament, in which he writes:

"Insects and diseases are not the real cause of plant diseases but only attack unsuitable varieties or crops imperfectly grown. Their true role is that of censors for pointing out the crops that

are improperly nourished and so keeping our agriculture up to the mark. In other words, the pests must be looked upon as nature's professors of agriculture: as an integral portion of any rational system of farming [...] The policy of protecting crops from pests by means of sprays, powders, and so forth is unscientific and unsound as, even when successful, such procedure merely preserves the unit and obscures the real problem – how to grow healthy crops" (Howard, 1943: p. 159).

Inspired by the work of Howard, King, McCarrison, and others, Lady Eve Balfour established what is thought to be the first long-term comparison of organic and nonorganic production, called the Haughley experiment (Stinner, 2007). Informed by her research and experimentation, she wrote her influential work The Living Soil (Balfour, 1943), which highlighted the importance of soil biota in nutrient availability. She became an integral founder and first president of the Soil Association in Britain in 1946. Rooted in both scientific and Christian values, Balfour was a strong proponent not only of healthy soils and foods, but also of the important social aspects of healthy farming communities (Conford, 2001). Another follower of Howard's work, Lord Walter Northbourne wrote Look to the Land, in which he is the first to use the term 'organic farming' (Northbourne, 1940). He uses the term both to refer to the use of organic material as fertilizer and amendment and to the idea of the farm as an organism, much like the language used by Steiner (Scofield, 1986).

In Japan, Mokichi Okada and Masanobu Fukuoka separately began to practice forms of what they called 'natural farming,' both based on principles of using natural fertilization, prohibiting the use of chemicals, and mimicking natural processes on the farm (Kristiansen and Merfield, 2006). Fukuoka practiced what he called 'do-nothing farming,' which aimed to minimize human interference with agricultural ecosystems in order to maintain the natural vitality of the field. Fukuoka published The One Straw Revolution in 1975, in which he outlines five principles: (1) cultivating the soil and the use of powered machines are unnecessary; (2) prepared fertilizers and the making of compost are unnecessary; (3) weeding, both mechanical and chemical, is unnecessary; (4) use of pesticides is unnecessary; and (5) pruning fruit trees is unnecessary (Fukuoka, 1978). Both men saw prepared fertilizers as weakening the natural vitality of the crops, and central to both men's philosophy was a spiritual element that unified farming, diet, and human well-being (Kristiansen and Merfield, 2006).

Much of the work being done in Europe was quick to impact the US, most notably through a man named Jerome Rodale. Rodale's interest in health and agriculture was first ignited when he heard a talk given by McCarrison in Pittsburg in the 1920s, and was later elaborated on when, as a publisher, he began what would become a close friendship with Howard (Conford, 2001). In 1940, Rodale purchased a farm in Emmaus, Pennsylvania, still the site of the Rodale Institute today, to begin practicing Howard's farming practices. In 1942, he began publishing the *Organic Farming and Gardening* magazine, and in 1945 he wrote Pay Dirt, in which he communicates the ideas of Howard, Steiner, and others to an American audience (Rodale, 1945). In his book, he also offers early criticisms of using chemical pesticides such as the newly marketed DDT. The Rodale Institute began its Farming System Trial in 1981 to compare a conventional grain rotation with an organic manure-based rotation and an organic cover-crop-based rotation (Stinner, 2007). It is now the world's second-longest running experiment comparing organically and conventionally managed plots, and the Rodale Institute continues to be an important research institute for organic and alternative farming practices (**Figure 1**).

Figure 1 Rodale Institute's ongoing Farming Systems Trial began in 1981. Photo © 2012 Rodale Institute.

The 1960s and 1970s were a time of significant social change in many regards, and also proved to be a transformative time for the organic movement. Rachel Carson's book, Silent Spring, transformed the dialog about the use of pesticides and other toxins, ultimately leading to the federal ban on DDT in the US in 1972 (Carson, 1962). A new perspective was gaining the global stage through books such as the influential Limits to Growth (Meadows *et al.*, 1972), which explores the limits of economics and resources to support a growing human population, and the then president of the Soil Association E. F. Schumacher's Small is Beautiful: A Study of Economics as if People Mattered (Schumacher, 1974), which introduces alternatives to capitalistic growth with a focus on human and environmental well-being (Kristiansen and Merfield, 2006).

Influenced by the British and German work on organic farming, organic thinking spread to France under the name 'agriculture biologique' (Vogt, 2007). Claude Aubert, author of the popular book, *L'Agriculture Biologique* (Aubert, 1970), helped found the French association Nature et Progrès. This activism in France led to the foundation of the International Federation of Organic Agriculture Movements (IFOAM) in Versailles in 1972. With the aim of creating an exchange network between the now numerous organic associations throughout the world, the founding organizations were the Soil Association in the UK, the Soil Association of South Africa, the Swedish Biodynamic Association, and the French Nature et Progrès (Geier, 2007). From its small roots, IFOAM quickly grew to become an important global network, promoting organic farming practices around the world, and setting basic global standards for organic practices.

In 1973, the Research Institute of Organic Agriculture (known by its German initials FiBL) was founded, and continues today to be the world's largest organic agriculture research establishment

(Niggli, 2007). Founded in part to answer questions about the scientific basis and economic viability of organic agriculture, in 1978 FiBL established the DOK trial to compare side-by-side biodynamic (D), organic (O), and conventional (K) plots. The DOK trial is now the longest-running comparison of organically and conventionally managed land in the world, and its results regularly continue to be published (Mäder *et al.*, 2002).

In the early days of IFOAM and the long-term cropping experiments of FiBL and the Rodale Institute, organic agriculture was still seen as a radical movement in many parts of the world. The United States Department of Agriculture (USDA) did not acknowledge organic farming as a noteworthy form of agriculture until the controversial publication of the USDA's Report and Recommendations on Organic Farming in 1980 (USDA, 1980). Carried out in conjunction with a survey of Rodale Press publication The New Farm readers, the report found comparable yields to most conventional acreage and slightly lower economic returns on organic land than conventional. The report's conclusions included remarks that fundamentally changed the national dialog on organic farming, including "it may be economical for some farmers to produce certain crops and livestock organically rather than conventionally" (p. 46), and "much can be learned from organic farming to reduce soil erosion and nonpoint source pollution"(p. 84).

The ensuing decade brought a new wave of dialog about organic agriculture in the US. The 1981 national meeting of the American Society of Agronomy, Crop Science Society of America, and the Soil Science Society of America included a significant discussion on organic agriculture and was recorded in a 1984 proceedings report entitled Organic Farming: Current Technology and its Role in a Sustainable Agriculture (Bezdicek *et al.*, 1984). A 1989 National Research Council report entitled Alternative Agriculture asserted that wider adoption of alternative farming systems such as organic farms "would result in even greater economic benefits to farmers and environmental gains for the nation" (National Research Council, 1989: p. 6). The organic farming movement in the US received a further boost with the passage of the Organic Foods Production Act in 1990, requiring the Secretary of Agriculture to develop a national list of prohibited substances in organic production, and paving the way for the USDA's National Organic Program. The year 1990 also coincided with Nicolas Lampkin's publication of his influential book, Organic Farming (Lampkin, 1990).

This momentum, which began in the 1970s, continues to grow even today. Widely read books such as Eric Schlosser's Fast Food Nation and Michael Pollan's The Omnivores Dilemma have dramatically increased the public's awareness of issues surrounding food and agriculture (Schlosser, 2001; Pollan, 2006). Popular films such as Supersize Me and Food, Inc. have also increased awareness of processed foods and the industrial food system and have left people seeking alternatives (Spurlock, 2004; Kenner, 2008).

Markets and Trends

Markets

Throughout most of the twentieth century, organic food was a small fraction of total food markets, limited to environmentally minded individuals and health-food proponents. Organic food was either sold directly from farms, or through health food stores and small cooperatives, and up until the early 1980s, organic food had global market shares of less than 0.1% (Aschemann *et al.*, 2007). The social changes that began in the 1960s led to the development of many certification schemes in the 1970s, as well as the foundation of IFOAM in 1972. These new organic certification programs allowed for quality assurance in a larger, less personal marketplace, and allowed for broader distribution of organically produced foods. In Europe sales of organic foods grew rapidly, and began to outpace the ability of small cooperatives and health-food stores to supply the growing demand. For these two reasons, the 1980s saw the entry of large supermarket chains into the organic foods market in Europe. It was not until the 1990s that a similar shift took place in the US, Japan, and Oceania. In almost every case, national sales of organic foods began to increase and even accelerate when conventional supermarkets began selling organic products (Aschemann *et al.*, 2007). The trend has largely continued into the twenty-first century, with Europe and North America consistently dominating the global market (**Figure 2**).

In 2010, Switzerland and Denmark spent the most on average per capita on organic foods, with the US and Canada also in the top 10 (**Figure 3**). Most countries have seen a large increase in per capita spending since 2000, with the exception of Denmark whose spending has been high throughout. Japan is one of the largest consumers of organic foods outside of Europe and North America, with the market for organic foods growing from US$350 million in 2002 to US$750 million in 2007 (Sahota, 2004; Sahota, 2007).

Geography

Land area under organic management had been steadily increasing in Europe since the 1980s (Willer and Yussefi, 2000), and has been expanding worldwide since the 1990s (**Figure 4**). Growth in organic land area in North America has lagged behind that of Europe, and still remains significantly lower proportionally. Despite growing domestic production of organic food, these countries have been relying increasingly on imported organic foods. In 2003, Germany and the UK imported 50% and 65%, respectively, of their organic food (Sligh and Christmann, 2003).

Increasing demands and expanding supermarket involvement with organic foods in Europe and North America has created a demand for more types of organic food, including tropical and out-of-season foods, and opened the market for growing and exporting organic foods in Africa, Latin America, and Oceania (Aschemann *et al.*, 2007). Organically managed land area in Oceania and Latin America increased dramatically in the 1990s and early 2000s, with the majority of land being extensively cattle-grazed rangeland. In 2004, Oceania and Latin America contained 42% and 24.2%, respectively, of the world's organic land, followed by Europe, with 23% (Yussefi, 2004). Although expanding more slowly, organic production in Africa and Asia has continued to grow through the past decade.

The strong majority of organic foods produced in the countries of Africa, Asia, and Latin America are exported to the

countries in Europe and North America, as well as to Japan (Lockie *et al.*, 2006). In Latin America, 90% of organic production is exported to the Northern Hemisphere (Garibay and Ugas, 2010). Africa's organic exports are largely destined for Europe (Bouagnimbeck, 2010). Although domestic sales of organically certified foods in these developing countries remain small, organic markets are emerging in urban areas such as Buenos Aires, São Paulo, Kampala, Nairobi, Dubai, and Kuwait City (Sahota, 2007; Sahota, 2010). In 2008, domestic organic food sales in Uganda and Kenya were estimated to be US $712 771 and US$397 351, respectively (Bouagnimbeck, 2010).

Motivations

As global and domestic markets and production have changed, so too have the motivations behind farmers choosing to farm

organically. Surveys from the early 1990s and prior have found environmentally motivated decisions to be the primary factors in adopting organic practices (Lotter, 2003). In a later study, Guthman (2001) observed price premiums to be the most often-cited reasons for converting into organic practices, contrasting with the motivations found just 10 years prior. Often these farmers follow the minimum standards for organic certification and downplay the agroecological elements of organic farming (Lotter, 2003). Willer and Yussefi (2000) describe additional reasons for the growing interest in organic farming in Africa besides price premiums: first, the disappointments with Green Revolution technologies have made some farmers more receptive to organic practices and second, many organic farming practices are comparable to or compatible with indigenous farming practices.

With more trust in organic certification, increasing popularity of organic foods, and limited supply, price premiums on organic foods are an important part of the organic market. Organic premiums are highly variable; a 2003 study reports premiums of 20–30% in Austria; 10–50% in Germany; and 0–100% in the US (Sligh and Christmann, 2003). In Denmark, there was little difference between organic and conventional prices. Price premiums are the result of higher production costs, limited supply, and as a mechanism to compensate farmers for environmental stewardship.

The top reasons given for consuming organic foods include health, environment, taste, and animal welfare (Lockie *et al.*, 2006). Furthermore, in the absence of standalone requirements for labeling foods produced from genetically modified organisms (GMOs), many consumers choose organic foods because they exclude GMOs. Lockie *et al.* (2006) identify the top barriers to consumption of organic foods, from most important to least, as follows: high prices, limited availability, distrust of product claims, food appearance, not being aware of organic food, and being content with existing choices.

Organic Certification

In the early days of organic agriculture, organic foods were sold either directly to consumers or in small markets, in which a farmer's organic practices were taken on trust and relationship between the producer and the consumer. As the market for organic foods expanded into larger supermarkets, and as organic foods were distributed across larger distances, the need for organic standards, certifications, and labels became

necessary. Organic certification provides verification that products are indeed produced according to certain standards. For consumers who want to buy organic foods, the organic certification standards ensure that they can be confident in knowing what they are buying. For farmers, these standards create clear guidelines on how to take advantage of the expanding demand for organic products. For the organic products industry, these standards provide an important marketing tool to help boost trade in organic products.

'Certified organic' means that the agricultural products have been grown and processed according to the specific standards of various international, national, state, or private certification organizations. Certifying agents review applications from farmers and processors for certification eligibility, and qualified inspectors conduct annual onsite inspections of their operations. Inspectors talk with producers and observe their production or processing practices to determine if they are in compliance with organic standards. Organic certification standards detail the methods, practices, and substances that can be used in producing and handling organic crops and livestock, as well as processed products.

Certification is not without its critics. Some argue that organic standards shift the emphasis to specific inputs and farming methods, and away from the more holistic process-based philosophies that gave birth to the organic movement (Ikerd, 2006). Some see certification as encouraging the conventional paradigm of maximizing production, without being specific enough about long-term sustainability goals (Ikerd, 2006). Others argue that national and global certification schemes do not account for important local and regional differences in farming systems, and that the cost of certification gives favor to large farms over small operations (Schmid, 2007). Finally, some point to the potential for organic standards to be diluted over time due to political and business interests.

In 1980, the IFOAM developed its Basic Standards for Organic Agriculture, which have since been periodically revised (Courville, 2006). IFOAM later established the IFOAM

Figure 5 European Commission's label for certified organic foods (European Commission, 2012).

Accreditation Program to provide international equivalency of certification bodies worldwide, and in 2011 a new program was launched, the IFOAM Family of Standards, in an effort to simplify harmonization across international bodies. In 2011, 61 certification bodies were either members of or in the application stages for the Family of Standards (IFOAM, 2012a). The other major international overseer of organic standards is the Codex Alimentarius Commission, created in 1961 by the Food and Agriculture Organization of the United Nations and the World Health Organization; the Commission's guidelines for the production, processing, labeling, and marketing of organically produced foods became effective in 2001 (Courville, 2006). Both IFOAM and the Codex Alimentarius Commission serve as global standards for certification programs worldwide.

Although several countries in Europe had existing certification programs, such as France's Agriculture Biologique label and Germany's Bioland label, the European Union (EU) developed a regulatory framework to oversee organic practices across all of Europe, beginning with the EU Council Regulation 2092/91 in 1991 (Schmid, 2007). These standards prohibit the use of synthetic pesticides and fertilizers, the use of growth hormones and antibiotics in livestock (with some exceptions for the sake of humane treatment), and the use of GMOs. New regulations went into effect in 2009 to place greater emphasis on environmental protection, animal welfare, and preservation of biodiversity (European Commission, 2012). The new regulations allow organic products to contain 5% nonorganic ingredients, a limit of 0.9% of unintentionally present genetically modified materials, and require organically certified foods to use the EU organic label (**Figure 5**).

As in Europe, individual states in the US had existing organic certification, such as the California Certified Organic Farmers, founded in 1973, when Congress passed the Organic Foods Production Act in 1990, charging the USDA with developing national standards for organic production. The USDA National Organic Program standards went into effect in 2002, setting standards for all food, domestic and imported, that is labeled 'organic,' and specifically prohibiting the use of genetic engineering methods, ionizing radiation, and sewage sludge for fertilization. The USDA National Organic Program

Figure 6 USDA National Organic Program's label for certified organic foods (USDA, 2012).

was established, and requires organic foods to be certified by a USDA-accredited third-party certifier, marked by the USDA organic foods label (**Figure 6**).

A 2010 survey found 488 organic certifiers worldwide, with only 10 certifiers in Africa and 164 in Asia (Rundgren, 2010). Seventy-three countries worldwide reported having national organic standards, with an additional 16 countries in the process of drafting legislation (Huber *et al.*, 2010).

An alternative to governmental or third-party certification, called Participatory Guarantee Systems (PGS), has been growing in popularity. PGS is designed for small farms and short supply chains, in which stakeholders verify producers' practices and hold them to the standards of a chosen certifier. They are designed to be less expensive and more locally focused, in order to be more accessible to small farms in developing and developed countries alike (IFOAM, 2012b). PGS is furthermore seen as returning to the local quality assurance systems built around social networks and trust on which the organic movement was founded (Katto-Aandrighetto, 2010). A recent survey estimates there to be approximately 10 000 farmers involved in PGS worldwide, with the majority in developing countries, as well as more than 800 in the US and approximately 500 in France (Katto-Aandrighetto, 2010).

Principles of Organic Farming

At its core, organic agriculture treats farms as whole organisms. Instead of seeing many pieces that can be treated in isolation (e.g., spraying pesticide for an insect outbreak, using herbicides for a weed control, or applying fertilizers solely for plant growth), the organic farm seeks to understand all the components of the agroecosystem in the context of one another. Organic farms try to strengthen the interconnections between components to achieve a self-managing, integrated agroecosystem similar to an organism or a natural ecosystem (Kristiansen and Merfield, 2006). Organic agriculture also treats humans as an integral component of the agricultural system, but not dominant in their control of the system. Agroecological systems are understood to be extremely complex, not fully understood or predictable, and therefore not able to be fully controlled. Humans are at once animals in the system, consuming products of the agroecosystem and returning wastes, as well as acting as managers of the system, making decisions on crop rotations, grazing, and soil management.

Many descriptions and principles of organic agriculture have been published over the past century (DARCOF, 2000).

Table 1 IFOAM principles of organic agriculture through time

1980 IFOAM Basic Principles
To work as much as possible within a closed system, and draw on local resources
To maintain the long-term fertility of soils
To avoid all forms of pollution that may result from agricultural techniques
To produce foodstuffs of high nutritional quality and sufficient quantity
To reduce the use of fossil energy in agricultural practice to a minimum
To give livestock conditions of life that conforms to their physiological needs and to humanitarian principles
To make it possible for agricultural producers to earn a living through their work and develop their potentialities as human beings
Current IFOAM Principles of Organic Agriculture
Principle of Health
Organic agriculture should sustain and enhance the health of soil, plants, animals, and humans as one and indivisible
Principle of Ecology
Organic agriculture should be based on living ecological systems and cycles, work with them, emulate them, and help sustain them
Principle of Fairness
Organic agriculture should build on relationships that ensure fairness with regard to the common environment and life opportunities
Principle of Care
Organic agriculture should be managed in a precautionary and responsible manner to protect the health and well-being of current and future generations and the environment

Source: Reproduced from Kristiansen, P., Merfield, C., 2006. Overview of organic agriculture. In: Kristiansen, P., Taji, A., Reganold, J. (Eds.), Organic Agriculture: A Global Perspective. Ithaca, NY: Comstock Publishing Associates, pp. 1–23 and IFOAM, 2012c. The principles of organic agriculture. International Federation of Organic Agriculture Movements. Available at: http://www.ifoam.org/en/organic-landmarks/principles-organic-agriculture (accessed 08.08.13).

IFOAM first published a set of basic principles of organic agriculture in 1980, a list that has been updated periodically (**Table 1**). The original principles are particular about the need for organic agriculture to be site-specific, to produce adequate food, to limit its environmental impact, to be socially just, and to be humane. IFOAM's current revised list includes only four general principles, putting more of an emphasis on interconnections and on social well-being.

The IFOAM principle of health emphasizes that environmental health and human health cannot be separated. Health is meant not to just mean a lack of illness, but rather an intact and thriving whole, including the health of humans, soils, crops, livestock, and surrounding environment. Emergent properties of a healthy and integrated agroecosystem include the system and the ability of its components to self-regulate and to exhibit resilience in the face of disturbance. By this principle, the use of synthetic pesticides, fertilizers, antibiotics, and additives is virtually banned for risk of negative health effects (IFOAM, 2012c).

The IFOAM principle of ecology states that organic agriculture should function in the same way that the natural ecosystems function. Central to this goal is the maintenance of biodiversity through diverse crop and livestock rotations, hedgerows, and wild areas. Agricultural systems should operate as a closed and integrated web of energy flows, nutrients dynamics, and biological interactions, with minimal losses and inputs to the system. Through this diversity of interactions emerge feedback mechanisms and self-regulating populations. In an intact agroecosystem, disease and pest outbreaks will be minimized through ecological balance, without the need for human intervention. Furthermore, agroecosystems must be managed and adopted in relation to its specific environmental, climatic, and social conditions (IFOAM, 2012c).

The IFOAM principle of fairness emphasizes organic agriculture's role in fostering equity, respect, and justice in every step of the food market. Workers, distributors, processors, and marketers are all to be treated with respect and paid fair wages. Animals are to be treated humanely, allowing them to live under natural conditions and exhibit their natural behavior. Furthermore, organic agriculture must be practiced in a way that is fair to future generations; it must conserve resources, maintain healthy ecosystems, and make decisions with long-term forethought (IFOAM, 2012c).

Finally, the IFOAM principle of care follows that organic agriculture has a responsibility to avoid risk of causing harm. This principle emphasizes that agriculture is practiced in the context of its environment, and has potential to impact its surroundings. IFOAM asserts that the use of new technologies should be limited until they are proven to be safe. Furthermore, although scientific knowledge and modern cost–benefit analyses are critical in agricultural practice, this principle also emphasizes the importance of traditional and indigenous knowledge in farming practice and in decision-making (IFOAM, 2012c).

The recent IFOAM revision resulted from concerns over lists of organic principles becoming overburdened with detail and lacking consistency (Kristiansen and Merfield, 2006). Numerous discussions have led to more general principles, such as those of the national survey carried out by the Danish Research Center for Organic Farming (DARCOF, 2000). The following is a list of specific principles, drawing from numerous efforts from around the world (USDA, 1980; DARCOF, 2000; Lotter, 2003; Kristiansen and Merfield, 2006; Gomiero *et al.*, 2011). It is not an exhaustive list, but is intended to illuminate specific principles that fall under the four general IFOAM categories described above.

- *Farm with the future in mind*: One of the central goals of organic farming is to conserve resources, protect natural habitats, and build soils, so that agriculture can be

sustained into the future. Organic agriculture offers one alternative to conventional agriculture, which with current rates of soil degradation, energy use, and pollution cannot be sustained in its current form.

- *Adapt to local conditions*: Being a complex agroecosystem, an organic farm must be adapted to its specific environmental, climatic, and social conditions. Crops and varieties are chosen based on soil, surrounding environment, climate, and the needs of the farmer and clientele. Specific crop rotations are designed for the needs of the soil, as well as weed and pest conditions (und Niemsdorff and Kristiansen, 2006).
- *Build and maintain healthy soils*: A central aim of organic agriculture is to build and maintain soils with high organic matter, long-term fertility, active and diverse biology, and minimal environmental losses due to erosion and nutrient runoff (Gomiero *et al.*, 2011). In contrast to conventional systems in which fertility is based largely on inorganic fertilizer additions, organic farms depend on biologically mediated fertility resulting from diverse soil microbiology and large stores of soil organic matter (Welbaum *et al.*, 2004). This is achieved most importantly by using organic nutrient sources (i.e., nutrients contained in carbon-based compounds) and avoiding the sole addition of inorganic nutrients (i.e., nutrients not coupled with carbon). The use of organic (carbon-coupled) nutrient sources such as compost, manure, and plant residues builds soil organic matter, and depends on the gradual biologically mediated decomposition of this organic matter into more plant-accessible inorganic forms of nutrients (Drinkwater and Snapp, 2007). The use of organic amendments can furthermore promote an abundant and diverse soil microbial population, which may lead to competition against soil pathogens (Letourneau and van Bruggen, 2006).
- *Conserve or enhance biodiversity*: In its effort to mimic natural ecosystems, an organic farm encourages biodiversity in its design and its management. A diversity of crops and livestock utilize different resources, attract different pests, compete differently with weeds, and increase income diversity. The use of long and diverse crop rotations – often 3–years or longer – is central to increasing this diversity over time and space. Additionally, many farms keep hedgerows and other semiwild areas that serve as habitat for insects, larger animals, and soil biota (Letourneau and van Bruggen, 2006). Increasing biological diversity – in flora, fauna, and soil microbiology – may increase the stability of the system, reducing outbreaks of pests and diseases (Shennan, 2008).
- *Integrate all components of the farm and close the nutrient cycle*: As an ecosystem, the organic farm is an interconnected network of components, each utilizing different resources and producing different waste products that serve as inputs for other components (**Figure 7**). The goal is a tightly integrated agroecosystem that minimizes its input requirements by recycling all waste products back into the farm. Composting wastes and returning them to the field is a central practice in organic farming. Mixed crop and livestock operations are also common in organic agriculture (Lampkin, 1990). Livestock feed on unused crop residues, control weeds, perform work, and return nutrients to the soil. One principle listed by IFOAM in 2004 was "to create a harmonious balance between crop production and animal husbandry" (Kristiansen and Merfield, 2006). Components can be integrated within a single farm, such as keeping livestock and raising crops together, or can be integrated over multiple farms in a region, with manure from one farm being exchanged for feed from another (Pearson, 2007). Other examples of on-farm integration include

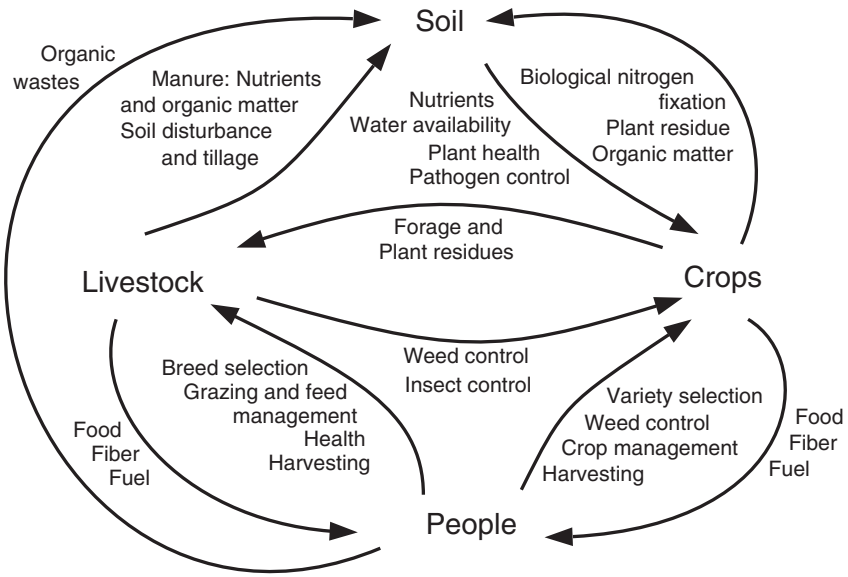

Figure 7 The integration and cycling of nutrients, energy, and materials through the components of an integrated organic farm. Adapted with permission from Stockdale, E.A., Lampkin, N.H., Hovi, M., *et al.*, 2001. Agronomic and environmental implications of organic farming systems. Advances in Agronomy 70, 261–327.

growing oil crops to use as fuel for tractors, and using methane biodigesters for power generation.

- *Reduce chemical and energy inputs and minimize losses*: Organic agriculture virtually prohibits the use of synthetic pesticides, herbicides, and fertilizers, seeks to minimize the use of fossil energy, and seeks to minimize nutrient losses and soil erosion. By integrating farm components and using long-term crop rotations, organic farms reduce weed, pest, and pathogen pressure, and thereby reduce the need for herbicides and pesticides. Natural controls, such as the use of diatomaceous earth for insects or the application of plant-based herbicides, are used occasionally as a last resort (Letourneau and van Bruggen, 2006). By recycling all materials and growing leguminous nitrogen-fixing crops and green manures, organic farms minimize the need for nutrient inputs. To replace nutrients lost with the export of crops, organic farms use biologically fixed nitrogen from green manures and cover crops supplemented with imported compost, animal manure, or rock minerals such as rock phosphate for phosphorous and greensand for potassium (und Niemsdorff and Kristiansen, 2006). Minimizing nutrient losses both keeps nutrients on the farm and limits atmospheric and surface water pollution. As previously discussed, the use of organic (carbon-coupled) nutrient sources such as compost, manure, and plant residues, plays a major role in reducing nutrient losses from organically managed farms (Drinkwater and Snapp, 2007). Nutrient losses are further minimized by planting perennial buffers to catch nutrient runoff and planting cover crops in fields to retain nutrients during wet periods of the year in which nutrient runoff is high (also called 'catch crops') (Lynch, 2009). The use of fossil fuel energy and its consequent greenhouse gas emissions are minimized on organic farms by avoiding the use of energy-intensive artificial nitrogen fertilizers, by selling locally and sourcing inputs locally, and occasionally using draft animal power instead of mechanical tractors.
- *Foster social well-being and animal welfare*: Organic agriculture aims to produce sufficient quantities of humanely raised, healthy food while treating and paying all workers fairly. Organic farms often produce foods for their community or region. Foods are produced without chemical additives or pesticides that may be unhealthy. Farmers should be able to support themselves and other workers with fair incomes, while maintaining safe and dignified working conditions. Furthermore, animals must be raised humanely under conditions that allow for the expression of their natural behaviors and needs. For example, USDA organic regulations require that livestock have access to the outdoors year round, that ruminants be raised on pasture, and that sick animals be treated as needed, even with the use of antibiotics if required (USDA, 2012).

Organic Farming Practices

Organic farms take maximum advantage of the synergistic interactions between their various farm enterprises. Instead of relying on prescriptive treatments for fertilization and crop protection, organic management practices depend on the complex interactions among soil fertility and biology, crop rotations, pest and weed populations, species diversity, and production (Figure 8). Diversified, location-specific crop rotations, often in combination with livestock grazing, are at the core of organic crop husbandry. The managerial goal of an organic farm is to use crop and livestock rotations to build soils and create an ecologically balanced community, such that the system is self-enriching, self-regulating, and requires a minimum of human intervention. The use of curative treatments, such as hand weeding or using natural pest deterrents, is often viewed as a secondary practice.

Soil and Fertility Management

Maintaining fertile and biologically active soils is at the core of managing an organic farm. Fertility in organic systems is derived predominantly from organic matter, such as compost,

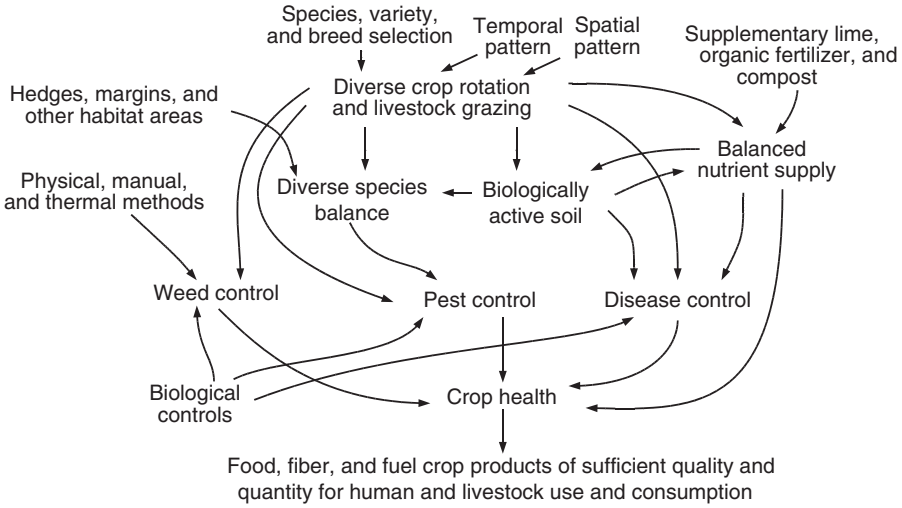

Figure 8 The integration of organic management practices. Adapted with permission from Stockdale, E.A., Lampkin, N.H., Hovi, M., *et al.*, 2001. Agronomic and environmental implications of organic farming systems. Advances in Agronomy 70, 261–327.

crop residues, manures, and other organic materials. Nutrients are made available slowly, as the soil biota mineralizes organic materials into smaller soluble compounds that can be taken up by plants. This biologically mediated gradual release of soluble nutrients can increase nutrient-use efficiency and reduce leaching losses (Drinkwater and Snapp, 2007). The addition of various organic materials may promote higher microbial abundance and enhance soil ecosystem processes (Shepherd *et al.*, 2002; Davis and Abbott, 2006). Furthermore, organic matter improves soil structure, increases its water storage capacity, and promotes tilth, or the physical condition, of the soil (Weil and Magdoff, 2004). The better the tilth, the more easily the soil can be tilled or direct-drilled with seed, and the easier it is for seedlings to emerge and for roots to extend downward. Water readily infiltrates soils with good tilth, thereby minimizing surface runoff and soil erosion.

Crop rotation – a sequence of different species of crop plants growing in the same field more than 2–4 or even more years – is critical in building soil organic matter and supporting a diverse soil biota. Crop rotations can be designed so that soil nutrient resources are used differently each season over the course of the rotation. Rotating crops for nutrient management may be especially important in organic systems in which nutrient availability is slow and biologically mediated. For example, crops that demand high levels of nitrogen might follow a leguminous crop that fixes nitrogen (und Niemsdorff and Kristiansen, 2006). Green manures and cover crops – plants grown solely to be returned to the soil – help to further diversify crop rotations, add large amounts of organic matter, and, in the case of leguminous crops, can fix nitrogen. Leguminous cover crops play an important role in supplying nitrogen through biological nitrogen fixation; some farms use on-farm biological nitrogen fixation to be self-sufficient in nitrogen (Reganold, 1988; Stockdale *et al.*, 2001). Cover crops are sometimes called 'catch-crops' when they are used to uptake and hold on to nutrients during periods of high leaching risk, such as winters with high precipitation. Nutrients are recycled throughout an organic farm wherever possible. Plant residues, processing wastes, and animal manure are composted and returned to fields.

Most farms rely on exporting crops and other products away from the farm, thereby exporting nutrients from the soil that must be replaced. Although a farm can fix its own nitrogen using leguminous green manures, other nutrients must be imported in the form of compost, manure, and other naturally occurring nutrient sources. Dried blood, bone meal, fish and seaweed extracts, and manures are common biological sources of macro- and micronutrients. Naturally formed rock minerals, such as limestone, gypsum, rock phosphate, elemental sulfur, and dolomite, are used as nutrient supplements and to adjust soil acidity. Limits and restrictions on the use of amendments are detailed in by individual certification programs.

Weed Management

Weed management is often cited as a primary challenge of organic farmers. Weeds can be especially challenging during periods of conversion to organic practices, during which weed populations are changing (Ngouajio and McGiffen, 2002).

Figure 9 Example of winter wheat intercropped with winter peas. Peas fix nitrogen and shade out weeds as the rows of wheat fill in and mature. Photo courtesy of Kristy Borrelli, Washington State University.

Crop rotations are designed to diversify resource competition against weeds, and to diversify timing and type of operations in which weeds can be controlled. Dense green manures, cover crops, and pasture phases of a rotation can compete against weeds, as well as providing a heavy mulch to physically suppress emergence (Bàrberi, 2002). Crops can be seeded with wide-row spacing to facilitate tillage and hand weeding between rows throughout the season; this practice is used especially with vegetable crops. Alternatively, higher planting densities can be more competitive against weeds and can limit their emergence, and are used for crops in which inter-row cultivation is difficult, such as with cereals (und Niemsdorff and Kristiansen, 2006). Other methods of increasing competition against weeds include intercropping, in which different crops are planted in an alternating manner, such that they maximize resource use and weed competition over space and time, and the use of a living mulch, in which a crop is undersown with a competitive cover crop (**Figure 9**). These crop layouts are designed to maximize the complementarity of resource use between the crops, minimize intercrop competition, and maximize interference with weeds, such as shading out emergent weeds and crowding out weed roots. Although these can be effective, challenges with decreased yields due to intercrop competition persist (Stockdale *et al.*, 2001).

In addition to these indirect weed management practices, which focus on diversifying crop rotation and improving crop-weed competition, organic farmers make use of numerous direct weed control practices. A variety of mulches, such as straw, cardboard, and plastic sheeting, are used to suppress weed emergence. Challenges of mulch include the high labor needs of applying the mulch, interference with crop growth and harvesting, nitrogen immobilization from carbon-rich mulches, and the heavy resource use of plastic mulch (und Niemsdorff and Kristiansen, 2006). After weeds have emerged, mechanical tillage is a common practice. Shallow cultivation, before planting or between rows, is common practice. Other cultivation methods are used under specific conditions and for specific crops, such as the use of harrows in postemergent cereal crops (Stockdale *et al.*, 2001). In mixed crop–livestock farms, animals are sometimes used to graze weeds instead

of cultivation. Thermal methods of weed control, such as flame- and steam-weeders, can effectively control emergent and preemergent weeds, but are energy intensive and can be expensive to operate. Solarization, heating the soil surface under clear plastic at temperatures high enough to kill weed seeds, is used in suitable climates, but can also be intensive in its use of materials and labor. Finally, an important method of weed control, especially on small farms, is hoeing and hand weeding. Although labor intensive, hand weeding has no capital cost and can be minimally invasive to crops.

Pest and Disease Management

As in any other agricultural system, basic best practices are critical to the success of an organic farm. These include the use of certified pathogen-free seed, selection of resistant crop varieties, effective crop rotations, residue management, and testing soils and plant tissues for pathogens (Cook, 2000). However, because organic farming focuses on whole system management and prohibits the use of synthetic insecticides, fungicides, and fumigants, organic management practices are largely preventative in nature, rather than reactive.

On a landscape scale, efforts are made to balance cropping land with noncropped and semiwild areas in order to maintain a diverse population of pests and their natural predators (Lampkin, 1990; Stockdale *et al.*, 2001). Field borders and hedgerows are often planted with flowering plants to attract a diversity of insects, and perennial species to attract larger insectivorous animals such as owls and bats. Efforts can be made to isolate fields of the same crop to limit the spread of crop-specific pests and diseases.

Niche diversity is also enhanced by crop rotations at a field scale. Intercropping, cover crops, and long diverse rotations are all used to disrupt pest life cycles and to support a diversity of pests and their natural predators. Certain pests and diseases can be avoided by planting crops at strategic times of the year to avoid pest and disease outbreaks in specific stages of plant growth (Letourneau and van Bruggen, 2006). Organic farmers can also select tillage methods, planting times, crop rotations, and plant-residue management practices to optimize the environment for beneficial insects that control pest species, or to deprive pests of a habitat or resources.

Plant root diseases are generally less severe in organic systems than in conventional systems (van Bruggen, 1995). This effect may be due to the functionally diverse soil biological communities found in organic systems (Stockdale *et al.*, 2001). Furthermore, the lack of excess nitrogen in organic systems, and the consequently low foliar nitrogen of crop plants, has been correlated with reduced disease and pest incidence in organic crops compared with conventional crops (Letourneau and van Bruggen, 2006).

Management practices on the scale of individual crops include selecting disease-resistant crop varieties, intercropping, and using biological controls. Severity of pests and diseases can sometimes be reduced with the higher within-field diversity of intercropping and living mulches (Letourneau and van Bruggen, 2006). Biological controls include introducing or promoting natural predators, parasites, or competitors that keep pest and pathogen populations below injurious levels. Specific soil treatments can be used to induce soils that are suppressive to pathogens. One such example is a recent research on the application of *Brassica napus* and *Brassica juncea* seed meal to control multiple pathogens responsible for apple replant disease (Mazzola and Brown, 2010).

Organically certified pesticides are typically used as a last resort to control insects and diseases, and are applied when pests are most vulnerable or when beneficial species and natural predators are least likely to be harmed. For example, diatomaceous earth is a powder made from crushed rock and is applied to the leaves of vegetables. Although harmless to humans, the edges of the particles lacerate the undersides of flea beetles and other insects. Another important fungal treatment on organic fruit farms is the use of sulfur sprays to control powdery mildew. Restrictions on the use of these natural fungicides and insecticides are detailed by individual certification programs.

Sustainability of Organic Farming Systems

A 2010 National Academy of Sciences report (National Research Council, 2010) defined four goals for a farming system to be sustainable: it must (1) supply abundant, affordable food, feed, fiber, and fuel, (2) be profitable, (3) enhance the natural resource base and environment, and (4) contribute to the well-being of farmers, farm workers, and rural communities. Just because a farm is organic does not mean that it is sustainable. For any farm to be sustainable, whether it is organic or conventional, it must meet all four sustainability goals. So, if an organic farm produces high yields of nutritious food and is environmentally friendly and energy efficient, but is not profitable, then it is not sustainable. Likewise, a conventional farm that meets all the sustainability criteria but pollutes a nearby river with sediment because of soil erosion is not sustainable. **Figure 10** illustrates the four sustainability goals and their overlapping areas representing the highest level of sustainability.

With the rise of organic farming worldwide, researchers are being presented with new opportunities to study organic

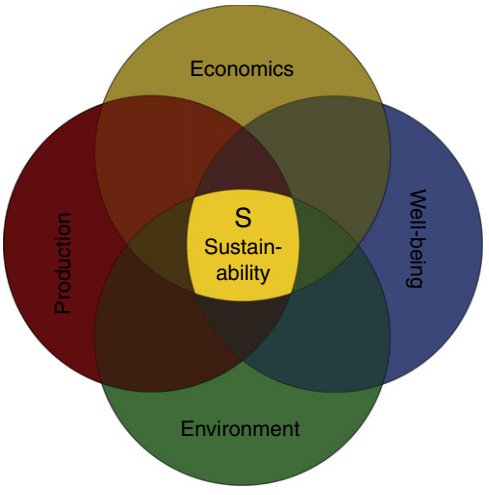

Figure 10 The four components of agricultural sustainability.

systems and also to compare them with their conventional counterparts. For example, organic farming systems provide an opportunity to link basic and applied ecology through research on biodiversity and ecosystem services (Letourneau and Bothwell, 2008). In addition, one can compare sustainability indicators, such as soil health, crop quality, and financial performance, of organic and conventional systems (Reganold, 2013). This section focuses on farming systems research comparing the sustainability of organic and conventional farming systems.

Examples of comparison studies that have helped shape farming systems research are the Corn Belt study (Lockeretz *et al.*, 1981), the Palouse erosion study (Reganold *et al.*, 1987), the South Dakota grain study (Smolik *et al.*, 1995), the Rodale Farming Systems Trial (Drinkwater *et al.*, 1998), the Washington State apple sustainability study (Reganold *et al.*, 2001), and the Swiss 'DOK' systems trial (Mäder *et al.*, 2002). To illustrate what is entailed in a multiple farming systems experiment measuring a large number of sustainability indicators, it is worth discussing the study by Reganold *et al.* (2001). In 1994, Reganold *et al.* (2001) established a 1.7-hectare replicated study of organic, conventional, and integrated apple production systems in a new commercial 'Golden Delicious' orchard in WA, USA. For six growing seasons (1994–99), five major sustainability indicators were measured: crop yield and quality, financial performance, soil quality, environmental impact of pesticides, and energy efficiency.

Although differences in annual apple yields were inconsistent among the systems, all three systems gave similar cumulative apple yields (**Figure 11(a)**). Organic apples were smaller, but sweeter and less tart, and as firm or firmer than were conventional and integrated apples. The organic system was more profitable based on breakeven points from enterprise budgets, followed by conventional and then integrated (**Figures 11(b)** and **(c)**). Receipts for integrated fruit were calculated using prices for conventional fruit. Receipts for organic fruit were estimated using prices for conventional fruit in 1995 and 1996 (the last year for transition to organic certification). Price premium to the grower for each grade of organic fruit (1997–99) averaged 50% above conventional prices. The breakeven point, when cumulative net returns equal cumulative costs, was 9, 15, and 17 years, respectively, for the organic, conventional, and integrated systems under actual fruit quality conditions (with significant apple russeting, a physiological skin disorder) (**Figure 11(b)**). When the economic analysis was adjusted by eliminating the effects of russeting, but maintaining the same size and grade and assuming a 15% cullage rate (average for Golden Delicious in Washington), the organic system was the most profitable in 1997 and 1998, and the breakeven points were much shorter (**Figure 11c**). For breakeven points of the organic and integrated systems to occur in the same year as the conventional system, price premiums of 12% for the organic system and 2% for the integrated system would be necessary under measured fruit quality conditions. Under nonrusseted fruit quality conditions, premiums of 14% for the organic system and 6% for the integrated system would be necessary to match the breakeven point of the conventional system.

Organic and integrated systems had higher soil quality than the conventional system (**Figure 11(d)**) mainly due to addition of compost and mulch in 1994 and 1995. Organic matter has a profound impact on soil quality, enhancing soil structure and fertility, and increasing water infiltration and storage. The conventional system ranked lowest because of a poorer ability to accommodate water entry and resist surface structure degradation. Compared with the organic system, the total potential negative environmental impact rating from the use of pesticides and fruit thinners was approximately 6× higher for the conventional system and 5× higher for the integrated system (**Figure 11(e)**). When a nonpheromone mating disruption conventional system was included for comparison, the conventional system was almost 8× higher than the organic. The organic system was 7% more energy efficient than the conventional system and 5% more efficient than the integrated system (**Figure 11(f)**). Major differences in energy inputs was higher weed control, insecticide, and fertilizer inputs for conventional and integrated systems, and higher fungicide and labor inputs for the organic system. On the basis of the results of all of these sustainability indicators, Reganold *et al.* (2001) concluded that the organic system ranked first in environmental and economic sustainability, the integrated system second, and the conventional system last. These results further suggest that integrated farming systems, which use a middle ground approach by blending organic and conventional practices, can achieve higher sustainability performance than conventional systems. For another example, Davis *et al.* (2012) found that two integrated maize/corn-based systems using small amounts of synthetic agrichemical inputs exceeded the overall sustainability performance of their less diverse conventional counterpart.

The results of the apple study (Reganold *et al.*, 2001) illustrate that, although crop yield and quality are important products of a farming system, the benefits of better soil and environmental quality provided by the organic and integrated production systems are equally valuable and usually overlooked in the marketplace. Such external benefits can come at a financial cost to growers. Currently, growers of more sustainable systems may be unable to maintain profitable enterprises without economic incentives, such as price premiums or subsidies for organic and integrated products that value these external benefits. Equally important, on incorporation of external costs into economic assessments of farming systems, it may be found that many currently profitable farming systems are uneconomical and therefore unsustainable. The challenge facing policymakers is to incorporate the value of ecosystem processes into the traditional marketplace, thereby supporting food producers in their attempts to employ sustainable practices.

What do other studies comparing organic and conventional farming tell us? Starting with the production goal of sustainability – that is, sufficient crop yields of high quality – yield differences between organic and conventional farming systems have been the topic of intensive debate. Although numerous individual studies have compared these yield differences, four have synthesized this information on a global scale. Stanhill (1990) was likely the first to conduct an extensive literature review of organic/conventional comparative yield data and found organic yields to be 9% lower than conventional yields in developed countries. Badgley *et al.* (2007) later found organic yields to be 8% lower in the developed world.

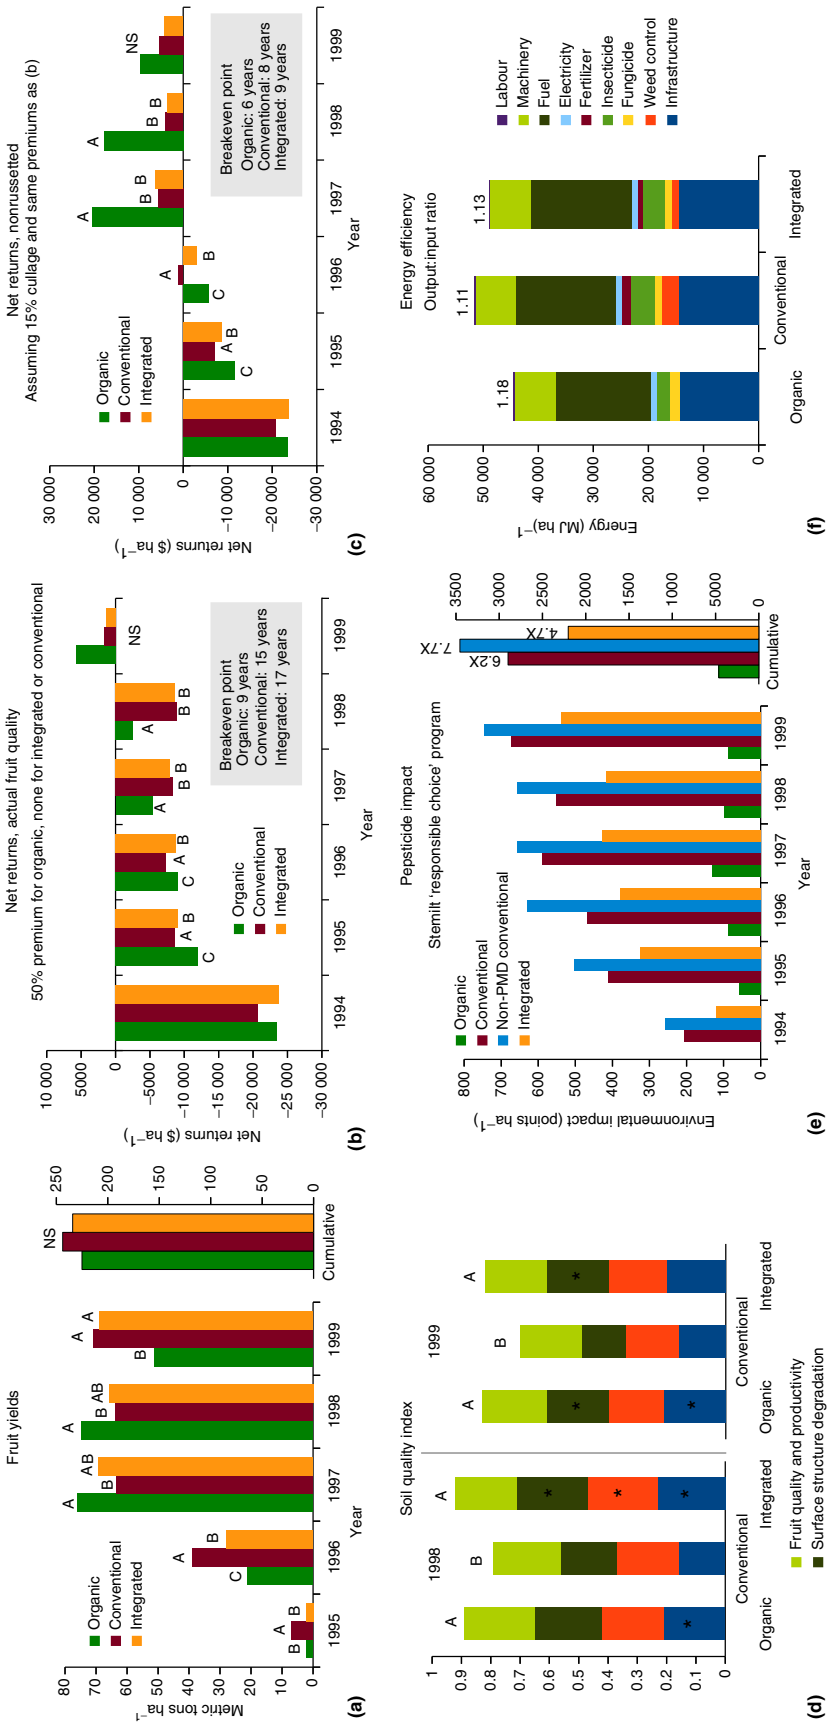

Figure 11 Sustainability indicators for the organic, conventional, and integrated apple treatments in the Reganold *et al.* (2001) study. (a) Shows annual and cumulative apple yields. (b) Shows annual net returns for actual fruit quality conditions, with breakeven points indicated. (c) Shows annual net returns for nonrusseted fruit quality conditions, with breakeven points indicated. (d) Shows soil quality index based on four equally weighted components: fruit quality and productivity, surface structure degradation, water movement and availability, and water infiltration. (e) Shows the potential negative environmental impact rating from the use of pesticides and fruit thinners using the Stemilt 'Responsible Choice Index,' (f) Shows energy efficiency (output/input ratios) based on energy accounting of output (yield) and all inputs.

In two recent metaanalysis studies of organic and conventional yield comparisons, de Ponti *et al.* (2012) found organic yields to be 21% lower in developed countries and 20% lower globally (362 yield comparisons), and Seufert *et al.* (2012) showed that organic farming systems had 20% lower yields in developed countries and 25% less when data from both developed and developing countries were combined (316 yield comparisons). However, these two studies also found that with certain crops, growing conditions and management practices, organic systems nearly matched conventional yields. For example, de Ponti *et al.* (2012) found that the best yielding organically grown crops are rice (6% lower than conventional), soybeans (8% lower), corn (11% lower), and grass-clover (11% lower). In comparison, the highest-yielding organic crops identified by Seufert *et al.* (2012) were organic fruits (3% lower yield than conventional), rain-fed legumes such as soybeans (5% lower), and oilseed crops (11% lower). One of the findings from the latter three studies (Badgley *et al.*, 2007; de Ponti *et al.*, 2012; Seufert *et al.*, 2012) is that most of the reliable, high-quality data are from developed countries, with there being a lack of solid quantitative data with appropriate scientific controls from developing countries.

Although metaanalysis is a great tool that can describe broad patterns not immediately visible in primary field research (Arnqvist and Wooster, 1995), it must also be treated with caution because no single farming system or practice works best everywhere (Reganold, 2012). Still, all four studies (Stanhill, 1990; Badgley *et al.*, 2007; de Ponti *et al.*, 2012; Seufert *et al.*, 2012) give strength to the argument that adoption of organic agriculture under agroecological conditions where it performs best may close the yield gap between organic and conventional systems. In addition, improvements in management techniques and crop varieties for organic systems may also close the yield gap between organic and conventional systems. For example, Murphy *et al.* (2007) found that direct selection of wheat cultivars in organic systems resulted in improved yields in organic systems when compared with indirect selection of wheat cultivars in conventional systems. In addition, as most agricultural research has historically been in support of conventional farming systems, more research directed at organic systems could show significant benefits in yields.

Crop quality can be divided into two parts: pesticide residues on foods and nutrition of foods. With the former, research has found that organic foods have significantly less pesticide residues (Baker *et al.*, 2002; Curl *et al.*, 2003; Lu *et al.*, 2006). For example, Baker *et al.* (2002) found that organically grown foods consistently had approximately one-third as many pesticide residues as conventionally grown foods, using data from three test programs: The Pesticide Data Program of the USDA; the Marketplace Surveillance Program of the California Department of Pesticide Regulation; and private tests by the Consumers Union, an independent testing organization.

With nutritional quality, although there is no universally accepted definition of what constitutes a nutritious food, recent scientific opinion has stressed that more nutritious foods are those that are more nutrient dense relative to their energy contents (Drewnowski, 2005). Although carbohydrates and fats are considered essential nutrients, the current concept of nutrient-dense foods, and hence more nutritious foods, places the emphasis on foods that contain more protein, fiber, vitamins, or minerals, as well as specific phytochemicals, such as the polyphenolic antioxidants found in fruits and vegetables (Scalbert *et al.*, 2005). In the past 12 years, at least 12 review studies (some being metaanalyses) of the scientific literature comparing the nutrition of organic and conventional foods have been published. Nine of these review studies (Soil Association, 2000; Brandt and Molgaard, 2001; Worthington, 2001; Williams, 2002; Magkos *et al.*, 2003; Rembialkowska, 2007; Benbrook *et al.*, 2008; Lairon, 2010; Brandt *et al.*, 2011) found some evidence of organic food being more nutritious, whereas three review articles (Bourn and Prescott, 2002; Dangour *et al.*, 2009; Smith-Spangler *et al.*, 2012) concluded that there were no consistent nutritional differences between organic and conventional foods.

Comparisons of foods from organic and conventional systems are often complicated by the interactive effects of farming practices, soil quality, plant varieties, and the time of harvest on nutritional quality. Hence, many of the comparative studies cited in some of the earlier reviews were not experimentally well designed to draw valid conclusions (Bourn and Prescott, 2002; Magkos *et al.*, 2003); for example, soils or crop varieties were not the same on each organic/conventional field pair. Nevertheless, studies, including recent reviews, have indicated that organic fruits and vegetables are generally more nutritious than their conventional counterparts, with the differences often being the higher antioxidant and vitamin C levels in the organic foods. The few studies that have compared organic and conventional foods for their organoleptic (sensory) properties have shown mixed results or used unreliable experimental designs (Bourn and Prescott, 2002; Rembialkowska, 2007).

There is growing evidence in the literature that adoption of organic farming systems produces financial benefits. However, transitioning to organic production (usually 3 years for crops) can be economically challenging and more information intensive. This transition period is generally, therefore, financially the most difficult time for organic farmers. After transition, the net return per hectare for organic compared with conventional farms is often equal or higher because of good yields and price premiums, as shown by numerous studies (e.g., Padel and Lampkin, 1994; Smolik *et al.*, 1995; Reganold *et al.*, 2001; Pimentel *et al.*, 2005; Cavigelli *et al.*, 2009). Net returns do not account for externalities, the importance of which is discussed previously. However, many European governments provide direct financial support for organic farmers in recognition of their farms' contribution to current policy objectives, including environmental protection, resource conservation, overproduction control, and reorientation of agriculture toward areas of market demand. Labor is higher with organic systems; it is often related to an increase in the diversity of enterprises on organic farms and sometimes to the development of new marketing and processing activities, rather than simply to increases in labor for specific crop or livestock enterprises (Padel and Lampkin, 1994).

For organic systems to be profitable, Zentner *et al.* (2011: 209–210) summarize that the main determinants "are the relative crop yields, extent of the cost savings due to the reduced reliance on nonrenewable resources and purchased inputs, the supply of unpaid family labor, the existence of price premiums for organic products and the magnitude and duration of

reduced income during the organic certification/transition period." MacRae *et al.* (2007) found that most organic farms in North America perform better financially under organic management compared with their previous tenure as conventional operations. They attribute this outcome to lower input costs, more diversified production and marketing channels, resilience in the face of variable market conditions, higher premiums, and a better capacity to adapt to weather extremes.

Research studies commonly support the general perception that organic farming systems are more environmentally friendly than conventional farming systems (Alföldi *et al.*, 2002; Kaspercyk and Knickel, 2006; Tuomisto *et al.*, 2012). Environmental benefits of organic agriculture include enhanced soil quality, which has been shown in numerous studies to be greater on organic than conventional farms or trials (Reganold *et al.*, 1993; Lotter, 2003; Gomiero *et al.*, 2011). For example, under organic management soil loss is greatly reduced (Reganold *et al.*, 1987; Gomiero *et al.*, 2011) and soil organic matter content increases (Mondelaers *et al.*, 2009; Gomiero *et al.*, 2011). Furthermore, organically managed soils generally have a higher water-holding capacity than conventionally managed soils, resulting in larger yields under conditions during drought periods (Lotter *et al.*, 2003; Gomiero *et al.*, 2011) (**Figure 12**). Soil biochemical and ecological characteristics are also improved (Mäder *et al.*, 2002; Lotter *et al.*, 2003; Gomiero *et al.*, 2011). For example, Reganold *et al.* (2010), in a comparison of numerous pairs of organic and conventional strawberry farms in California, not only found organically farmed soils to have better soil quality based on traditional soil characteristics, but also to exhibit greater numbers of endemic genes and greater functional gene abundance and diversity for several biogeochemical processes, such as nitrogen fixation and pesticide degradation; they were able to conclude that the higher quality soils on the organic strawberry farms may have a greater microbial functional capability and resilience to stress. Owing to these features, soils farmed organically are healthier than those farmed conventionally for passing on to future generations.

Figure 12 Plots in the Rodale Institute's Farming Systems Trial during a drought in 1995. Corn is planted in a legume-based treatment (left) and a conventional treatment (right). Photo © 2012 Rodale Institute.

In a metaanalysis of environmental quality parameters in organic and conventional farming comparison studies, Mondelaers *et al.* (2009) concluded organic farming contributes positively to agrobiodiversity (breeds used by the farmers) and natural biodiversity (wildlife). For example, Mäder *et al.* (2002) found organic systems to have higher below- and above-ground biodiversity than conventional systems in a long-term trial in Switzerland. Studies discussed in Kristiansen *et al.* (2006) showed that organic farms generally have more plant diversity (30–350% increase in floral species diversity in organic fields in Europe), greater faunal diversity (insects, soil fauna and microbes, and birds), and often more habitat and landscape diversity on organic farms.

As organic agriculture uses virtually no synthetic pesticides, there is no risk of synthetic pesticide pollution of ground and surface waters (Alföldi *et al.*, 2002). Concerning the impact of the organic farming system on nitrate and phosphorous leaching and greenhouse gas emissions, Mondelaers *et al.* (2009) found that organic farming systems score better than conventional farming for these items when expressed per production area; however, given the lower land-use efficiency of organic farming in developed countries, this positive effect is less pronounced or not present at all when expressed per unit product. In a summary of several nitrate leaching studies from organic and conventional farming comparisons in Germany and The Netherlands, Alföldi *et al.* (2002) found that nitrate leaching rates per hectare are significantly lower in organic farming systems. In the US, Kramer *et al.* (2006) found that annual nitrate leaching was 4.4–5.6 times higher in conventional apple orchard plots than in organic apple orchard plots. In a metaanalysis of environmental quality parameters in organic and conventional farming comparison studies, Tuomisto *et al.* (2012) found organic farms to have lower nitrate leaching, nitrous oxide emissions, and ammonia emissions per unit of field area but higher per product unit for the same three parameters.

Using a model of riverine nitrogen export for 18 Lake Michigan Basin watersheds based on nitrogen budgets at 5-year intervals from 1974 to 1992, Han *et al.* (2009) reported that if farmers choose organic practices and reduce fertilizer use, nitrogen export levels by rivers could decrease to below present-day levels. They projected future nitrogen fluxes under three land-use and two climate scenarios: (1) business as usual, (2) increased dependence on organic farming, (3) increased fertilizer use from corn-based ethanol production, (4) a 5% increase in rainfall, and (5) a 10% increase in rainfall. The study revealed that the combined effect of 10% more rainfall and more ethanol production would increase nitrogen levels in rivers by 24%. However, increased use of organic farming practices could reduce nitrogen levels in rivers by 7%, even if rainfall increased by 10% (Han *et al.*, 2009). Reducing nutrient and pesticide pollution to aquatic and marine systems – especially as there are more than 400 dead zones today – is an added environmental benefit of organic farming systems.

Organic systems have been shown to usually be more energy efficient (ratio of energy output or yield to input) than their conventional counterparts (Lockeretz *et al.*, 1981; Reganold *et al.*, 2001; Alföldi *et al.*, 2002; Kaspercyk and Knickel, 2006; Tuomisto *et al.*, 2012). For example, Alföldi *et al.* (2002) summarized numerous comparison studies on

energy consumption both per hectare and per unit of output (tons) for different crops from organic and conventional farming systems in Germany, Italy, Sweden, and Switzerland. On a per hectare scale, all organic farms had a significantly lower energy consumption than their conventional counterparts. For organic winter wheat (three studies), citrus (one study), olive (one study), and milk (two studies), energy consumption per output unit was lower relative to conventional production, but not for organic potatoes (in two out of three studies) and apples (one study), where energy consumption per output unit was higher (Alföldi *et al.*, 2002).

Comparison research studies comparing organic and conventional farming systems for the social aspects of agricultural sustainability are scarce despite their importance in providing farmers with knowledge to design systems that balance different social sustainability goals to improve overall sustainability (National Research Council, 2010). Studies on social sustainability are difficult to conduct and complicated because social dimensions are influenced by the behavior of farmers and consumers, values of community members, and market and policy conditions. Such studies are needed to discover how well organic, conventional, and other farming systems are doing in, for example, adequately compensating farm workers in an equitable way and contributing to building strong rural communities.

Are there significant differences in social sustainability indicators of organic and conventional farming systems? MacRae *et al.* (2007) found some evidence in North America that when a community has many sustainable (including organic) producers, there are positive shifts in community economic development and social interaction; the reasons appear to be related to the need to hire more labor, the increased demand for local goods and services, and a greater commitment to participate in civic institutions.

Future of Organic Farming

Organic farming offers one alternative to conventional agriculture at a time of increasing concern over global climate change, water scarcity, diminishing resources, water and air pollution, and issues of food quality and access. Organic farming systems offer many sustainability benefits in energy-efficiency, environmental viability, productivity, and stability. Reliance on recycled organic wastes such as compost and manure means these nutrients are kept out of the waste stream and used on the farm to build soil (Pearson, 2007). The use of these organic amendments increases water-holding capacity, which can lead to more robust yields under conditions of water scarcity, an important factor in a changing climate (Lotter *et al.*, 2003). Using organic fertilizers reduces nutrient leaching losses, while eliminating the high-energy requirements of producing synthetic fertilizers (Drinkwater and Snapp, 2007). Furthermore, organic farming principles value and integrate indigenous knowledge, diversify local food supplies, and advocate for fair worker conditions (Kristiansen *et al.*, 2006).

Concerns over the meaning and rigor of organic practices persist, however, as the organic food trade becomes increasingly global and corporate in nature. The expanding market for organic food may lead to increased specialization, a loss of crop diversity, and simplified crop rotations, all contrasting with commonly accepted best practices of organic agriculture (Ikerd, 2006). Long-distance trade of organic foods separates consumers from producers and processors, can lead to a lack of transparency and certifier oversight, and ruptures regional nutrient cycling. Some argue that concerns over ecological justice, land appropriation, resource rights, and worker compensation are not being adequately addressed by organic agricultural movements (Halberg *et al.*, 2007). Furthermore, certification requirements may not adequately address the need for organic farming systems to be highly catered to local ecological and social conditions. However, although challenges exist in implementing meaningful organic standards, the development of organic certification programs has played an important role in increasing sales and production of organic foods worldwide and continues to maintain minimum standards for organic practices (Aschemann *et al.*, 2007).

Significant barriers to farmers adopting organic practices remain. In parts of the world, some individuals and organizations hold strong cultural biases against the connotations of organic agriculture, which can limit the spread of organic practices (Wheeler, 2008). Many areas, especially rural regions and developing countries, have a lack of access to markets for organic foods or infrastructure for storage and distribution. Some governments and nongovernmental organizations are making efforts to eliminate these barriers, such as the international course recently developed by the United Nations Capacity Building Task Force on Trade, Environment, and Development called Successful Organic Production and Export (Naqvi and Kaukab, 2010). Certification costs imposed by certifying agencies can be an additional barrier, and the transition period into organic certification can be a risk to farmers, with little experience in organic management and rapidly changing weed and fertility conditions.

Policy can play an important role in encouraging organic farming practices. For example, policies can support the development of research and technology that is applicable to organic farms, governments can remove or change agricultural subsidies to support organic farms, and regulations can be developed to limit the overuse of fertilizers or synthetic pesticides (Kristiansen *et al.*, 2006; Reganold *et al.*, 2011).

Furthermore, organic farming is knowledge intensive and relies on an intimate understanding of ecological processes. Organic farming is biologically mediated, with nutrient supplies mediated by the mineralization of soil organic matter, and is therefore inherently complex and unpredictable (Drinkwater and Snapp, 2007). Kristiansen *et al.* (2006) emphasize the importance of creating knowledge networks and educational frameworks to help farmers in their transition to organic practices. Additionally, a relative dearth of research on organic systems over the past century compared with conventional systems has left organic agriculture at a disadvantage (Lotter, 2003).

Coordinated whole-system research comparing organically and conventionally managed farms in a variety of geographical locations is needed to better understand the impacts of different fertilization and pesticide regimes on biodiversity,

ecological functions, and nutrient dynamics. The factors affecting soil biota and their influence on ecological processes are not well understood, and are especially important in understanding soil fertility, crop productivity, and disease dynamics on organic farms (Reganold *et al.*, 2010). Furthermore, research is needed on the effects of climate – specifically of location-specific climate change scenarios – on soil organic matter, nutrient dynamics, and gas emissions from organic farming systems (Kaspercyk and Knickel, 2006). More research is needed in developing countries on ecosystem services and social impacts of organic farming (Halberg *et al.*, 2007). Finally, research on the role of organic agriculture in global food security, food access, and nutrition is in its early stages and must be developed further (Stockdale *et al.*, 2001).

If one wants to feed a growing world population, producing adequate yields is vital. However, as described earlier, sufficient productivity is only one of the four main goals that must be met for agriculture to be sustainable. Mainstream conventional farming systems have provided growing supplies of food and other products, but often at the expense of the other three sustainability goals – economic, environmental, and social. Although organic farming may generally have lower yields, a US National Research Council Report (2010) identified organic farming as one of the several innovative, more diverse systems that better integrate production, environmental, and socioeconomic objectives. Other innovative systems include agroforestry, integrated or hybrid organic/conventional, conservation agriculture, grass-fed livestock production, and mixed crop/livestock systems. No one agricultural system alone will safely feed the planet. Rather, a blend of these and other innovative farming systems will be needed for future global food and ecosystem security. Research studies discussed here indicate that organic farming can play a significant role in feeding the world. Yet, only approximately 1% of global agricultural land is now managed organically (Willer, 2011). Owing to the multiple sustainability benefits of organic agriculture, this percentage should be much larger in the future.

Glossary

Agroecosystem Within a commercial farm system, basic ecological processes – competition, herbivory, and predation remain but are overlaid and regulated by agricultural processes of cultivation, subsidy, control, harvesting, and marketing. In contrast to ecosystems, processes are not self-regulatory but require stockmanship to steer and regulate the processes on the various scales.

Certification A determination made by a certifying agent that a production or handling operation is in compliance with the regulations in this part, which is documented by a certificate of organic operation.

Ecosystem An ecological community that consists of all the organisms in an area – plants, animals, and microbes – interacting with one another and with their physical environment.

Labeling All written, printed, or graphic materials accompanying an agricultural product at any time or written, printed, or graphic materials about the agricultural product displayed at retail stores.

Organic (1) Belonging to a superordinate whole (system) in which the single parts (subsystems) are closely related to one another.

Organic (2) A labeling term that refers to an agricultural product produced in accordance with the regulations in this part.

Production diseases Diseases that are multifactorial by origin and represent a negative side effect of livestock production primarily caused by an inappropriate farm management. Fertility disorders, infectious diseases such as mastitis and pneumonia, lameness, and metabolic disorders represent the main production diseases within dairy and pig production farming throughout the world.

Qualitative growth A process during which resource productivity increases but the resource use decreases. This is possible because knowledge and immaterial services are substituted for material resources and manual work.

Sustainability The ability of agroecosystems to maintain productivity when it is subject to a major disturbing force. It determines the persistence or durability of an agroecosystem's productivity under known or possible conditions and is a function of the intrinsic characteristics of the agroecosystem, of the nature and strength of the stresses or shocks to which it is subject, and of the human inputs that may be introduced to counter these stresses and shocks.

System approach A line of thought in the management field that stresses the interactive nature and interdependence of external and internal factors within a system. It integrates analytical and synergistic methods, encompassing both top–down and bottom–up approaches.

Introduction

Organic livestock production is an integrated and integrative part of organic agriculture. In comparison with other agricultural fields, it is a fairly new approach within agriculture and agricultural science. Thus, the availability of on-farm experiences as well as scientific knowledge, elaborated by various disciplines, is comparably low. Nevertheless, a review of numerous research works that have been conducted in the past might provide enough knowledge to risk at least some conclusions about what has been developed and achieved so far.

Organic livestock production is not practiced on an island but is surrounded and influenced in many different ways by the developments in conventional livestock production. Accordingly, there is a large area of intersection between both production methods, which might be even bigger than the differences between them. Although the development of organic livestock production occurs worldwide, the focus of this article is on the situation in Europe and the United States, where the longest experiences are available and most of the research work has been conducted.

To understand organic livestock farming, it is necessary to consider the initial conditions, how it has developed as an alternative to the predominant approach, and which driving forces have been involved to arouse the considerable increase in the number of organic farms. Further questions of interest address the differences between organic and conventional livestock farming with respect to their potentials and obstacles, regarding not only the performance capacity of the farm animals but also the qualitative outcomes in terms of product and process qualities from the different production methods. Furthermore, it is worth reflecting on this concept by introducing the leading ideas and the principles highlighted by the representative organizations and by assessing whether the practices of organic livestock farming correspond to the principles. Additionally, the constraints and the defaults where organic livestock production was not able to achieve its own claims so far have to be looked at.

Last but not least, the system approach is introduced as an access to the complexity that emerges from the interconnectedness between the various factors within the farm system. Following a different approach, organic livestock production not only is interesting in itself but also offers a point of view that enables the perception of mainstream agriculture from a distant position and at the same time promotes a critical debate between both approaches in an ongoing process of changing perspectives. As a result, the observer might gain additional knowledge that goes beyond conventional and organic agriculture.

Finally, the main question is what can be learnt from the different approaches of organic livestock production, what has proven to be of overall benefit and hence should be expanded, and what has failed to provide good solutions and therefore should no longer be emulated when facing an increasing necessity to put agriculture on the right track to sustainability.

Short Historical Retrospective

The beginnings of organic agriculture, reviewed among others by Schaumann (2002), Lockeretz (2007), and Youngberg and DeMuth (2013), can be associated with Arthur Young (1770), defining a 'well-proportioned farm,' followed among others by Justus von Liebig (1803–73), with his recommendations for a 'balanced crop rotation,' and Albert Howard (1873–1947), explaining an 'applied agricultural ecology.' Rudolf Steiner (1861–1925) and Hans Müller (1891–1988), who developed the concept of Biological Dynamic Agriculture and Organic Biological Agriculture, respectively, were further outstanding pioneers of the concept of Organic Agriculture. These pioneers and also the first private associations of organic agriculture, such as the Demeter Association and the Soil Association founded in 1924 in Germany and in 1946 in the United Kingdom, respectively, had their topical focus on soil biology and plant production, whereas farm animals played, if at all, only a marginal role, primarily as suppliers of organic manure.

Many pioneers of organic farming argued that soil quality is the key to long-term sustainable agriculture (Reganold *et al.*, 1990). They believed that synthetic chemical fertilizers and pesticides (and the monocultural cropping systems that these materials permit) disrupted the sensitive balance of organic matter, beneficial microbial and biological activity, and micro- and macronutrients, thus requiring ever-increasing applications of artificial compounds. There was also the widely held belief that food produced in artificially fertilized soils had less nutritive value and was likely to have toxic pesticide residues. Soil quality was the foundation that supported a number of additional core beliefs, such as the proper way to structure a farm enterprise so as to optimize soil health, the health of farm crops and animals, and the health of those families who lived on the farm or who consumed the food produced.

Guidelines have been a characteristic feature of organic farming since 1954 because trademark legislation in Germany required clear criteria to identify organically produced goods (Schaumann, 2002). As the variety of production sites and the resulting product properties did not allow their identification to be linked to products qualitatively in terms that could be described exactly and understood analytically, the production method itself became the identifying criterion for labeling organic food. This fundamental principle has been kept to the present day in private standards and meanwhile has been adopted by legislators in many countries of the world.

In the United States, the first-ever USDA-authorized investigation of organic agriculture was conducted by the USDA Study Team on Organic Farming (1980), elaborating the following definition:

"Organic farming is a production system which avoids or largely excludes the use of synthetically compounded fertilizers, pesticides, growth regulators, and livestock feed additives. To the maximum extent feasible, organic farming systems rely upon crop rotations, crop residues, animal manures, legumes, green manures, off-farm organic wastes, mechanical cultivation, mineral-bearing rocks, and aspects of biological pest control to maintain soil productivity and tilth, to supply plant nutrients, and to control insects, weeds, and other pests."

This definition helps to understand that organic farming in former times was nearly exclusively explained from the perspective of plant production while particular claims and requirements of farm animals were not considered. Also the founders of the International Federation of Organic Agriculture Movement (IFOAM) took this approach in 1982 when aiming to guide worldwide standard settings.

In early 1990, the Organic Foods Production Act (OFPA, 1990) was introduced, provided for establishing a USDA 'organically produced' label for products meeting a strict set of national standards and guidelines and counteracting against a misuse to the word as goods labeled organic often sell at premium prices, which increases the temptation. Ultimately, the OFPA became part of the 1990 Farm Bill. However, disputes between the organic industry and the USDA, and disagreements within the industry itself over the meaning of specific provisions of the bill, delayed its implementation until 2002 (Youngberg and DeMuth, 2013).

In the European Union, organic farming has been governed since 1991 by the EEC Regulation 2092/91 (EC, 1991) setting out the rules for labeling a food product as 'organic' or the equivalent terms 'biological' or 'ecological' in other languages. The Regulation was developed to harmonize the rules of organic crop production across member states, to protect the consumers from unjustified claims, to avoid unfair competition between those who label their products as organic, and to ensure equal conditions for all operators. The result was a legally enforceable and officially recognized common standard for crop production, certification, and labeling in the European Union, setting a minimum standard for all organic systems across EU member states although allowing the private sector to maintain stricter rules.

Although it was officially intended by the EU Commission to supplement production rules for organic livestock production shortly after those for crop production, it took the European member states 8 years to finally agree on rules for organic livestock production (EC, 1999), thus supplementing Regulation no. 2092/91 on organic production and becoming law in August 2000. The considerable delay reflects the challenges that the EU Commission had to deal with when trying to share a common idea of organic livestock production in the face of very complex and heterogeneous production processes and manifold areas of conflicting aims. An increasing awareness of the different stakeholders in the different European countries with regard to the possible advantages and disadvantages for the interests of national operators made it excessively difficult to agree on a common regulation.

Although the official implementations of organic standards can be seen as milestones of a long-lasting process, which to some degree summarized the corresponding stage of the process, they should not distract one from the fact that the on-farm practices developed quite confusingly and largely heterogeneously. Organic farming has never been and will

never be organized uniformly, neither with respect to the various objectives nor in the degree of their implementation. This heterogeneity is a common attribute with conventional farming. There have been and still are different perspectives on organic agriculture with different understandings of what it is and what it develops. Alroe and Noel (2008) identified protest (negation of certain aspects of modern mainstream agriculture), meaning, self-creating movement (entity or network with certain goals and principles), and market niche (based on standards) as the most significant perspectives on organic agriculture that cannot be merged into one but can be helpful in understanding its past and its future development.

It can be summarized that organic farming has its historical roots in efforts to establish alternatives to mainstream agriculture primarily in the fields of soil biology and plant production while livestock production played only a marginal role in the view of the organic pioneers.

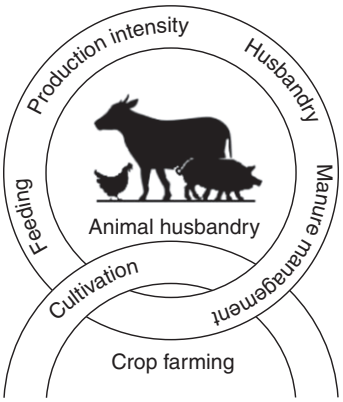

Figure 1 Need for reorganization of the farm system when striving for self-sufficiency.

Initiation of Organic Livestock Production

The Regulation (EEC) 1804/99 (EC, 1999) historically marks the beginning of organic livestock production in farm practice in Europe. In the time before this Regulation was put into force, only a few single aspects regarding the livestock issue have been formulated by private organic organizations, inspired by the basic norms of IFOAM. Even in 2000, only 3 from the 17 basic objectives of organic agriculture, defined by the general assembly of the IFOAM (2000), dealt more or less with the topic of organic livestock production: maintenance of biodiversity, freedom and access to possibilities for the execution of natural behavior, and balanced mix of crop and livestock production.

From a scientific perspective, a first definition of organic livestock production was provided by Sundrum (1998), addressing the need to focus not only on standards but also on general objectives to be envisaged by the production method: "Organic livestock production is based on the voluntary self-restriction in the use of specific means of production with the objectives to produce food of high quality in an animal appropriate and environmentally friendly manner within a nearly complete nutrient farm cycle."

Taking into account the standards in plant production, the emphasis of the considerations was placed on the need for an intensive adaptation process. For instance, the ban of mineral nitrogen fertilizer and the cultivation of legumes for nitrogen fixation require to adapt the crop rotation not only according to the demands of plants and soil biology but also according to the nutrient requirements of the farm animals in their various stages and depending on their performance levels when striving for a high level of self-sufficiency (**Figure 1**).

Correspondingly, conversion to organic farming demands a comprehensive reorganization within the farm structure where the needs of plant cultivation have to be balanced with the requirements of livestock production, whereas stocking density and animal performance have to be adapted to the nutrient potential of the homegrown feedstuffs. The need for restructuring the farm system is, among others, enforced by the ban of chemically synthesized feed (enclosing extracted soybean meal) and feed additives (e.g., synthetic amino acids and growth promoters).

The voluntary self-restriction in the use of external nutrients goes along with limitations with respect to the possible performance levels and the productivity on the average level of an animal while the farm management is encouraged to improve the productivity on the farm level and within the farm system by achieving the best possible efficiency in the use of homegrown resources.

From the very beginning, the low-input strategy of organic livestock production has to compete with the high-input strategy of conventional production; the latter striving for a decrease in production costs in the first place, mainly by increasing the stock and the stocking density as well as the performance level. Therefore, it should be comprehensible that a strategy based on self-restriction in the use of relevant external production tools, primarily intended to decrease production costs per product unit, cannot compete on the base of production costs. Necessarily, organic livestock production has to strive for alternatives to compensate for lower yields and higher production costs by focusing on quality instead of purely quantitative traits. Qualitative traits and added values are a precondition to gain and to justify premium prices that enable a reliable farmer's income. Consumers are asked to pay premium prices not only for a specific quality of the products of animals' origin but also for the production process itself defined and distinguished as different process qualities according to the expected outcome of the production process in terms of a high status of animal health and welfare and a high level of environmentally friendly production.

Correspondingly, potentials of the alternative strategy have to be balanced by the farm management toward various disadvantages. Potentials can be seen among others in the inherent incentive to increase the efficiency in the use of homegrown nutrient resources, being less dependent on external resources and their price developments, incentives to improve preventive strategies with respect to the occurrence of animal diseases because of restrictions in the use of medical remedies. Furthermore, lower performance levels are expected to reduce the risk for metabolic disorders and those diseases that develop from metabolic disorders, for example, due to an impaired immune competence. Overall, potentials lie in the

elaboration of synergetic effects when adapting processes to the local conditions and to natural processes for reasons of a more resilient system that is able to compensate for changing deficits, either in the availability of nutrients or in the case of changing market prices, thus developing strategies for qualitative growth. Instead of striving for general solutions, farm-specific optimization strategies have to be developed.

It is in the nature of the complex processes that the organic approach requires high management skills. The farm manager must be capable of gaining an overall picture of the complex interactions within a farming system. One has to make available the use of a comprehensive dataset of information about the internal processes on the various stages within the farm system, to reflect on the most relevant factors, to implement feedback mechanisms, and to guide the production process.

Further constraints are due to the fact that conflicting aims that occur when facing a limited availability of resources have to be solved within the farm system and cannot be easily outsourced by purchasing external input. Thus, organic farmers are more restricted by the local production conditions than is generally the case in conventional production. Above all, organic farmers are depending on the willingness of consumers to pay premium prices that are high enough to cover the expenditures and the farmers' income. Correspondingly, organic livestock production has to take into account the demands and perspectives of consumers to a high degree. As with conventional farmers, organic farmers share the concerns about inadequate low market prices.

According to the EC Regulation 1804/99, labeling food of animal origin as being 'organic' identifies the products as deriving from a production method defined by guidelines and minimum standards, intended to ensure quality production rather than maximizing production. The Regulation includes specifications for the conversion process, housing conditions, animal nutrition, care and breeding, disease prevention, and veterinary treatment, while creating frameworks for organic livestock production and product labeling, referring to the whole farm as the base of a comprehensive farm system. Since its introduction, various slight amendments to the regulation have been passed.

According to Padel *et al.* (2009), the EC Regulation 1804/99 defined organic livestock farming by the practices rather than the principles and ethical values. That is why the authors see a widespread concern that core organic values of organic agriculture are not well represented in standards and especially in governmental regulations that set only minimum standards for all organic producers.

In 2002, the US National Organic Program (NOP) Regulation was put into force, also encompassing among others numerous specifications about the handling, feeding, and treatment of farm animals. In the following years, other countries also followed the examples of the European Union and United States. However, organic livestock farming practices and certification requirements vary worldwide. All of these have in common that farm animals are fed organically produced feed that is cultivated without the use of mineral N-fertilizer, pesticides, and genetically modified organisms and their derivative (IFOAM, 2005). They are reared without the preventive use of antibiotics or growth hormones. They are provided outdoor access, direct sunlight, fresh air, and freedom of movement.

The US concept seems to be more consumer driven ('pure' food, produced without the use of antibiotics), whereas the European approach considers not only the health aspects of the food but also the animal welfare aspects as important issues. Detailed information on the differences between international organic standards is provided by Schmid *et al.* (2008).

Besides statutory minimum standards, organic farming, represented by the general assembly of the IFOAM, commits itself to a number of substantial values and thereby sets itself apart from conventional farming. During the assembly in the year 2006, the members of IFOAM adopted four principles: Health, Ecology, Fairness, and Care, which grew out of stakeholder consultations. According to the preamble, they represent a vision to improve agriculture in a global context. The value elements covered by these principles include the integrative values of sustainability, naturalness, and a system approach (IFOAM, 2005).

Summing up, organic livestock production follows a clearly different approach than mainstream of animal production when striving for a high level of self-sufficiency and a high level of product and process quality to justify premium prices, which are essential to cover higher production costs.

Framework Conditions of Organic Livestock Farming

Some of the most relevant standards in relation to livestock production are outlined below. If not separately highlighted, they are based on the Regulations, enforced in Europe (EC, 2007, 2008).

According to the Regulation, livestock production is fundamental to the organization of agricultural production on organic holdings in so far as it provides the necessary organic matter and nutrients for cultivated land and accordingly contributes toward soil improvement and the development of sustainable agriculture.

Animals should have, whenever possible, access to open air or grazing areas. Organic stock farming should respect high animal welfare standards and meet animal species-specific behavioral needs whereas animal health management should be based on disease prevention. Disease prevention shall be based on breed and strain selection, husbandry management practices, high quality feed and sufficiently opportunity to exercise, appropriate stocking density, and adequate housing maintained in hygienic conditions. Moreover, the choice of breeds should take account of their capacity to adapt to local conditions. Organic livestock shall be born and raised on organic holdings. Husbandry practices and housing conditions shall ensure that the developmental, physiological, and ethological needs of animals are met. It shall primarily obtain feed for livestock from the holding where the animals are kept or from other organic holdings in the same region. Livestock shall be fed with organic feed that meets the animal's nutritional requirements at the various stages of its development. Part of the ration may contain feed from holdings that are in conversion to organic farming. Further details with respect to housing, feeding, mutilation, and treatment are discussed in the following paragraphs.

Table 1 Comparison between the EC-Council Directives and the EC-Regulation on organic livestock farming (EC 1804/1999) in relation to minimum standards concerning the housing conditions

Farm animals	*EEC-Council Directives on protection of farm animals*	*EEC Regulation on organic livestock farming*
Dairy cows	No Council Directives	
Locomotion area[a]		6.0 m^2 indoors + 4.5 m^2 outdoors
Floor characteristics		Lying space with litter (bedding)
Husbandry practices		Keeping tethered is forbidden
Calves		
Locomotion area[a]	1.3 m^2	1.5 m^2 indoors + 1.1 m^2 outdoors
Floor characteristics	Dry litter bedding[c]	Dry litter bedding
Husbandry practices	Group penning after 8 weeks	Generally group penning
Sow with piglets		
Locomotion area[a]		7.5 m^2 indoors + 5.0 m^2 outdoors
Floor characteristics	Isolated and nonperforated floor	Dry litter bedding
Fattening pigs		
Locomotion area[a]	0.65 m^2[b]	1.3 m^2 indoors[b] + 1.0 m^2 outdoors
Floor characteristics	Safe floors	Dry litter bedding
Husbandry practices	Tools for occupation > 1 h	No tail docking and tooth clipping
Laying hens		
Locomotion area	450 cm^2	1660 cm^2 indoors + 4 m^2 outdoors

[a]Area per animal.
[b]Up to 110 kg live weight.
[c]For calves up to 2 weeks of age.

Housing

Specific housing conditions should serve a high level of animal welfare, which has priority in organic livestock farming and therefore may go beyond community welfare standards that apply to farming in general. Concerning the indoor area provided for livestock in organic farming, the EEC Regulation goes far beyond the current space allowance in conventional production with respect to different species. In addition, the indoor area is supplemented by an outdoor area that has to be at least 75% of the indoor area. Furthermore, organic livestock are not allowed to be kept tethered or in individual confinement housing. The comparison between the EC-Council Directives and the EC-Regulation on organic livestock farming (EC 1804/1999) in relation to minimum standards concerning the housing conditions is presented in Table 1.

Although beef cattle, pigs, and poultry in conventional systems are frequently housed in unbedded systems with partly or fully slatted floors, all farm animals in organic farming must be provided with litter. Completely slatted floors are forbidden. In addition to its role as a cushioned physical surface, the provision of straw is expected to reduce health and welfare hazards through its role as a behavioral substrate.

Piglets shall not be kept on flat decks or in piglet cages. Exercise areas shall permit dunging and rooting by porcine animals. For the purposes of rooting, different substrates can be used.

Organic husbandry practices should prevent poultry from being reared too quickly. Therefore, specific provisions to avoid intensive rearing methods should be laid down. In particular, poultry shall either be reared until they reach a minimum age or shall come from slow-growing poultry strains, so that in either case there is no incentive to use intensive rearing methods.

Feeding

Livestock should be fed on fodder produced in accordance with the rules of organic farming, preferably coming from the farmer's own holding, by taking into account their physiological needs. In the case of herbivores, at least 50% of the feed shall come from the farm unit itself or in case this is not feasible it should be produced in cooperation with other organic farms primarily in the same region.

All young mammals shall be fed on maternal milk in preference to natural milk, for a minimum period of 3 months for bovines, 45 days for sheep and goats, and 40 days for pigs.

At least 60% of the dry matter in daily rations of herbivores shall consist of roughage, fresh or dried fodder, or silage. A reduction to 50% for animals in dairy production for a maximum period of 3 months in early lactation is allowed. Roughage, fresh or dried fodder, or silage shall be added to the daily ration for pigs and poultry. Growth promoters and synthetic amino acids shall not be used. The feed is supposed to be free of genetically modified material.

Mutilation

In contrast to conventional livestock production, where several surgical mutilations are carried out as a matter of routine in farm animals, including castration, dehorning, tail docking, and beak trimming, mutilations are widely banned in organic livestock farming and are restricted to derogations that require separate permission by the certifying bodies. An exception is the castration of male pigs that is also practiced to a large extent in organic pig farming. However, from the beginning of the year 2012, castration of piglets has to be carried out with the application of anesthesia or analgesia

(EC, 2008), which differs from the current practices in conventional production.

Treatment

Where animals become sick or injured they shall be treated immediately, if necessary in isolation and in suitable housing. The preventive use of chemically synthesized allopathic medicinal products is not permitted. In organic farming, phytotherapeutic essences and homeopathic products shall be used in preference to chemically synthesized allopathic medicinal products or antibiotics, provided that their therapeutic effect is effective for the species of animal and the condition for which the treatment is intended. It is emphasized that if the use of the authorized substances and measures is not effective and if the treatment is essential to avoid suffering or distress, chemically synthesized products may be used with some limitations. With the exception of vaccinations, treatments for parasites and compulsory eradication schemes where an animal or group of animals receive more than three courses of treatment with chemically synthesized allopathic veterinary medicinal products or antibiotics within 12 months, or more than one course of treatment if their productive lifecycle is less than 1 year, the livestock concerned, or produce derived from them, may not be sold as organic products, and the livestock shall undergo the conversion periods.

The withdrawal period between the last administration of an allopathic veterinary medicinal product to an animal under normal conditions of use and the production of organically produced foodstuffs from such animals is to be twice the legal withdrawal period.

Although some overlap exists between European and US organic standards, there are some key differences. On organic livestock farms in the United States, animals or products from animals given NOP-prohibited substances may no longer be sold as organic, and these animals must then be removed from the herd. However, producers are prohibited from withholding necessary treatment from a sick or injured animal (USDA National Organic Program, 2011).

Practices of Organic Livestock Farming

As all organic farms are obliged to follow the same minimum standards, one might expect a high level of uniformity in the living conditions of farm animals, at least higher than in the nondefined conventional commercial farms, and a more homogeneous outcome with respect to traits of product and process quality (e.g., animal health status). Several aspects contradict with this expectation.

Production conditions of organic livestock farming in Europe vary from outdoor production to indoor production and encompass huge differences between countries and regions, not only in relation to environmental conditions and the genotype used but also in relation to the nutrient supply and the management measures (Vaarst *et al.*, 2006; Sundrum, 2010). Housing conditions encompass largely varying options with respect to space allowance, group size, climate and air conditions, etc., depending on the farm-specific and local conditions. Although most organic farmers make use of conventional breeds and genotypes, a large variation in the performance level and in the nutrient resources used is found. Although feeding rations should be based in the first place on homegrown feedstuffs, they provide a higher variability in ingredients and composition than is expected in the case of fodder from feed mills (Sundrum *et al.*, 2008).

In the United States, organic dairy production practices require access to pasture suitable to the stage of production, climate, and environment. Sato *et al.* (2005) reported that 76% of conventional herds included in his study had some access to pasture, whereas 50% of the organic herds utilized intensive rotational grazing, in contrast to only 7% of the neighboring conventional herds. In the United States, lactating cows in organic dairies in Michigan, Minnesota, New York, and Wisconsin were more likely to be housed in tie stalls, whereas most conventional dairies housed cows in free stalls and milked in a parlor (Zwald *et al.*, 2004). Compared with conventional farms, organic farms typically house their animals in older housing during the winter months (Ruegg, 2009). In general, conventional farms tend to be bigger, produce more milk, feed more grain, have longer calving intervals, and have younger cows than their organic counterparts (Zwald *et al.*, 2004; Stiglbauer *et al.*, 2013).

An epidemiological study based on 101 pig herds in 6 European countries revealed that farmers differed widely in their feeding regimes, in the implementation of disinfection measures, the use of clinical examination of the individual pigs, separation of diseased from healthy animals, presence of the farmer during farrowing, and with regard to routine measures such as castration, grinding teeth, and iron supply of piglets (Sundrum *et al.*, 2010).

Although the literature on organic dairy and pig production indicates a large heterogeneity of the living conditions of farm animals, the development of conventional livestock systems shows a clear trend to closely controlled environments. Living conditions have typically been adopted across regions and countries to maximize aspects of animal productivity, thereby increasing environmental homogeneity between farms and leading to the predominance of a small number of breeds and genotypes that are particularly productive under these specific conditions. Parallel to the increasing performance of livestock, nutrient demands have increased the call for the use of particularly energy- and protein-rich concentrate to meet the nutrient requirements of the animals at their various life stages. The equipment of indoor housing and the feeding ration is offered by specialized enterprises, becoming more and more standardized all over the world.

On organic farms the income is often provided by profits from the livestock sector. The majority of 550 farms surveyed in 11 EU countries generated their income mainly from one category of enterprise, such as grazing livestock (50%), arable crops (20%), permanent crops (7%), horticulture (3%), or intensive livestock (3%), whereas 17% are ruled as mixed farms (Nieberg *et al.*, 2005).

In the United States, organic dairy products comprise 15% of total organic sales, and organic fruits and vegetables account for 38% of total sales, making them the top 2 sectors of organic food (Organic Trade Association, 2010). From 2000 to 2008, the number of certified organic cows in the United States

increased from 38 196 to 249 766 (USDA Economic Research Service, 2008).

Summing up, the living conditions of farm animals in organic livestock farming are largely heterogeneous. Although common ideas and guidelines exist only on a meta-level, the concrete implementation in farm practice results in a large variety of stocking densities, performance levels, nutrient availabilities, housing conditions, and hygiene measures. Thus, low input and highly intensified farms mark the cornerstones of different objectives, various priorities, and diverse living conditions for farm animals in organic agriculture.

Consumers' Perspectives

In face of the heterogeneity, questions arise whether the outcome of the production processes meet the expectations of consumers. Consumers' concern over the quality and safety of conventional food has intensified in recent years and primarily drives the increasing demand for organically grown food, which is perceived as healthier and safer (Magkos *et al.*, 2006). Consumers express concern about possible hormone, antibiotic, pesticide, or chemical residues in animal products. A survey commissioned by an organic cooperative indicated that 70% of US consumers expressed at least moderate concern about health risks associated with use of pesticides and antibiotics in food production (Roper Public Affairs, 2004). Concern for human health and safety as a key factor influencing consumers' preference for organic food is consistent with observed deterioration in human health over time and therefore motivates consumers to buy organic food as insurance and investment in health (Yiridoe *et al.*, 2005). Organic products are marketed to lessen these concerns by requiring that farm animals are raised using a whole systems approach that includes the use of organic feeds (grown without use of pesticides or synthetic fertilizers), no usage of antibiotics or growth hormones, and emphasis on husbandry practices that limit stress and promote health.

However, as literature reviews revealed (Woese *et al.*, 1997; Yiridoe *et al.*, 2005), consumers purchase organic food for very different reasons. Aside from concerns about human health, this includes the effects of conventional farming practices on the environment and perceptions that organic foods are tastier than their conventional alternatives. Particularly in Europe, more and more consumers expect their food to be produced with greater respect for the needs of farm animals. Many consumers associate organic farming directly with enhanced animal health and welfare and conflate organic and animal-friendly products (Harper and Makatouni, 2002; McEachern and Willock, 2004). Thus, for many people, organic farming appears to be a superior alternative to conventional livestock production (Hughner *et al.*, 2007). Consumers' interests and expectations are linked to their willingness to pay premium prices on products (Zanoli, 2004). In contrast, consumers are less strongly motivated by the altruistic concerns of environmental protection and the support for rural society – the so-called public goods.

Even though organic farming covers only a small percentage of the food market, the expressed liking in the general public appears far greater than the market share. Interest in organic food has grown remarkably as consumers react to popular media about health effects and then have gradually evolved attitudes toward the origins and to the production process of food. For example, a change from confinement to grazing systems is one of the tools to evoke positive associations with the product. In this way, animal health and welfare have been turned into quality attributes of food.

However, not only the word 'health' but also the word 'organic' means many different things to different consumers. Correspondingly, consumers of organic foods are homogeneous neither in demographics nor in beliefs (Hughner *et al.*, 2007; Aertsens *et al.*, 2009; Martelli, 2009). They hold a huge variety of motivations, perceptions, and attitudes regarding organic foods and their consumption (Yiridoe *et al.*, 2005). Although consumers typically understand the broad issues about organic foods, many tend not to understand the complexities and niceties of organic farming practices and organic food quality attributes. Furthermore, there is a reason to assume that consumers delegate responsibility for ethical issues in food production to the retailer or the government as many consumers do not like to be reminded about issues connected with the animal when choosing products of animal origin (Skarstad *et al.*, 2007). Moreover, knowledge of production systems often appears of little importance for food market potentials as some consumer groups often freely remark that there is no link between the negative images of production methods and consumers' purchase behavior (Ngapo *et al.*, 2003). According to the authors, consumer groups are often confused and they mistrust the limited information available at the point of purchase, whereas price is an extremely visible attribute of products related to quality by the notion of value (McEachern and Schröder, 2002). Demand tends to depend more on the price differential with respect to conventionally grown products than on actual price. In contrast to sensitivity of demand to changes in price, income elasticity of demand for organic foods is generally small (Martelli, 2009).

Summing up, the decision-making process to buy organic food of animal origin is driven by many different factors, from which expectations regarding 'healthy' products show the highest priority. However, neither are consumers a uniform group covering common interests nor are they experts who can decide on how to evaluate product and process qualities and what is needed to provide framework conditions that are appropriate to ensure quality production.

Gap Between Theory and Practices

By following the practices set out in the standards, the farmers make a promise to the consumer to deliver added values, beyond the legal minimum standards for conventional agriculture and food (Padel *et al.*, 2009). The question arises to what degree organic livestock farms are capable to fulfill these demands. In the following, a preliminary assessment is given regarding the issues of animal behavior, animal health, product quality, and the use of antibiotics.

Animal Behavior

When considering demands of livestock in organic farming, possibilities to execute natural behavior patterns have been

one of the first objectives, implemented in private regulations asking for instance to provide access to pasture in the summer season for dairy cows. Minimum standards refined in legally binding regulations in relation to animal welfare are primarily focused on the locomotion area, floor characteristics, and husbandry practices. In Europe, dry litter as well as group penning is prescribed for all farm animals. Tethering of farm animals and completely slatted floors are forbidden. Comparing the organic standards with those in conventional production (minimal standards of the Council Directives) and private branded programs, Sundrum (1999) concluded that they reach a clearly higher level and enable the execution of behavioral patterns to a far higher degree. In addition, the regulations prescribe a regular check of the standards by independent certifiers, providing an additional advantage in comparison to conventional ordinances.

Close confinement of farm animals raise welfare concerns into both physical and behavioral issues. Physical concerns arise from the consequences of lack of exercise, such as leg weakness, skin lesions, and lameness (Ruis-Heutinck *et al.*, 2000; Buchwalder and Huber-Eicher, 2004). Enlarging the locomotion area and providing litter bedding is expected to provide substantial benefits for farm animals (Hindhede *et al.*, 1996; Guy *et al.*, 2002). In the case of pigs, the litter bedding can be eaten to provide gut fill and rooted to permit appropriate expression of foraging behavior. This generally prevents the development of stereotyped tail-biting behavior and reduces social aggression (Meunier-Salaün *et al.*, 2001). Furthermore, the prescription to provide roughage in the daily diet of pigs can reduce risk of constipation and gastric ulcers and increase satiety from increased feeding time and greater physical bulk in the gut (Stewart and Boyle, 2008).

Although raising the level of minimal standards is suited to improve the living conditions, a higher level of minimal standards cannot be treated as equivalent to appropriate livestock housing conditions and high welfare status for different reasons (Sundrum, 2000). However, minimum standards represent only a small section of the interrelationship between farm animals and their living conditions. Besides the housing conditions, the quality of stockmanship and management, the patterns of feeding, climatic factors, and the hygienic situation all have significant influences on animal health and welfare of farm animals. Owing to differences in genetic origin, age, sex, or in the experiences during ontogenesis, farm animals can vary widely in their requirements in relation to the housing conditions. Furthermore, it is well known that poor quality straw bedding can contain high levels of mycotoxins, which causes health and reproductive disorders. Moreover, increased use of straw, especially in deep litter systems, is a significant risk factor for endoparasites (Nansen and Roepstorff, 1999; Haugegaard, 2010). Keeping farm animals in outdoor systems potentially has both advantages and disadvantages. Greater space and environmental diversity permit expression of a wider range of behavior and health challenges may be reduced by the lower animal density and better air quality; however, there are also negative influences of reduced biosecurity, contact with wildlife disease reservoirs, and increased numbers of endoparasites, some of which can only be transmitted outdoors (Redbo *et al.*, 1996; Edwards, 2005; Van de Weerd *et al.*, 2009).

Summing up, the higher level of the minimum standards concerning the housing conditions in organic livestock farming and their regular check provide clearly improved preconditions for the behavior of farm animals compared with the conventional situation.

Animal Health Status

Most production diseases emerge from a multifactorial etiology, meaning that various factors contribute to the occurrence of disease. In addition to pathogens and animal-related conditions, other contributing factors (housing, feeding, hygiene, etc.) may be considered as stressors in the environment, disturbing homeostasis in the animal. Owing to the various interactions between health-influencing factors, the assessment of animal health status on the herd level faces a high level of complexity. In the literature, huge differences and intercountry variation exist in study designs and in definitions of diseases (LeBlanc *et al.*, 2006).

The status of animal health in organic livestock farming on the farm level has been described in various reviews, mainly addressing the European situation. In this context, animal health is primarily related to the occurrence of production diseases. The reviews cover different species (Cabaret, 2003; Hovi *et al.*, 2003; Thamsborg *et al.*, 2004), dairy cows (Vaarst *et al.*, 2008; Sundrum, 2012a), pigs (Sundrum *et al.*, 2010; Sundrum, 2012b), or poultry (Tuyttens *et al.*, 2008; Van de Weerd *et al.*, 2009). Available reviews concerning the health status in organic herds in the United States are narrowed down mainly to dairy production, focusing on mastitis in the first place (Sato *et al.*, 2005; Ruegg, 2009; Cicconi-Hogan *et al.*, 2013) or also include ketosis and pneumonia (Richert *et al.*, 2013a).

Studies that have compared health performance in conventional and organic farms have shown that disease problems tend to be similar to what is found under conventional conditions although the extent of these problems varies considerably among farms (Thamsborg *et al.*, 2004), and between countries (Vaarst *et al.*, 2008). As differences between farms appear to be greater than those between production methods, organic livestock farming defined by minimum standards does not provide a homogeneous outcome with respect to the animal health status (Sundrum *et al.*, 2006). The reviews clearly indicate that organic standards do not automatically lead to a high status of animal health that exceeds the level in conventional production.

Sources of variation in relation to animal health attributes are due to the numerous interactions between genotype, age, sex, nutrient supply, housing conditions, care, and their varying impacts on the dynamic nature of animal health status. Thus, it primarily depends on the management as to whether the potentials for a high level of animal health are fully realized. Differences in management practices, restrictions in the availability of resources (such as labor time and financial budget), and a lack of feedback and control mechanism within the farm system appear to be primary reasons for the substantial variation.

Fertility disorders, mastitis, lameness, and metabolic disorders represent the main production diseases within dairy

farming throughout the world (Rushton, 2009). These are multifactorial by origin and indicate an overstrained capacity of the farm animals to cope with the living conditions provided by the farm management (Gröhn *et al.*, 1998).

The level of production diseases in organic livestock production have been the issue of various studies. Brinkmann and March (2011) investigated the animal health status of 50 organic dairy farms in Germany in the years 2002–03 and with the same approach in 2005 on 43 farms. The mean incidence rates of mastitis were 33% (0–101%) in the first and 29% (2–81%) in the second study. Prevalence rates of lameness averaged 18% (2–53%) and 20% (4–53%) in the first and second study, respectively. The frequency of metabolic disorders showed a large variation between farms. Mean incidences rates of hypocalcemia showed 5.9% in the first and 10.2% in the second study. In contrast, the incidence rates of ketosis and acidosis were on average below 2% in both studies. Bennedsgard *et al.* (2010) found hypocalcemia in organic dairy farms to occur on an average level of 12%. 74 organic dairy farmers in Germany were asked for disease incidences on their farm (Hörning *et al.*, 2005). Those mentioned as regular or frequent were 44.6% for udder health problems, 31.1% for fertility disorders, and 36.4% for claw health problems. Somatic cell counts (SCC) in the bulk tank averaged to 223 000 cells ml^{-1} of milk. According to Roesch *et al.* (2007), cow-level prevalence of subclinical mastitis in dairy cows in Swiss organic production systems for visits at 31 days and 102 days postpartum were 39% and 40%, respectively. In a study on Swedish organic herds, the most common reason overall for culling was poor udder health followed by low fertility and leg problems (Ahlman *et al.*, 2011).

In the United States, mean SCC from previous 3 months in the bulk tank of organic farms were 221 000 cells ml^{-1} (Stiglbauer *et al.*, 2013). In a study by Cicconi-Hogan *et al.* (2013), the presence of *Staphylococcus aureus* in the bulk tank milk was higher on organic farms (61%) than on conventional farms (42%), confirming previous studies (Sato *et al.*, 2005; Pol and Ruegg, 2007). In this context, it is noteworthy that in a comprehensive study based on the analysis of 615,187 quarter foremilk samples, in 83% of all samples with SCC > 100 000 cells ml^{-1} mastitis pathogens were detected, indicating a case of mastitis (Schwarz *et al.*, 2010).

The results of slaughter animal and carcass inspection were evaluated by Machold *et al.* (2005) in the case of pigs and cattle reared in organic and conventional production systems, respectively. The most common pathological findings in pigs were liver diseases, condemned carcasses, and lesions of the tail tip. In cattle the most common pathological findings were claw and leg disorders; diseases of liver, kidney, and pleura; and parasitic infections. From cattle reared in organic systems, less carcasses, livers, and kidneys were discarded in comparison with conventional cattle. Pigs from organic systems showed similar incidence of 'milk spots' in the liver caused by *Ascaris suum*. There was no pronounced difference concerning the number of condemned carcasses and the incidence of tail tip lesions between pigs from organic and conventional farms.

Another study showed that in a lower proportion of the organic pigs, abnormalities were detected in the lungs, 53.0% versus 58.6% among conventional pigs, whereas 64% of the livers from organic pigs showed milk spots, whereas 43% of the conventional livers were affected (Sundrum and Ebke, 2004). A further study, 10 years later at the same abattoir, revealed that the situation concerning the pathological findings from organic pigs had not improved (Hoischen-Taubner and Sundrum, 2013).

Living conditions found in practice are so multiform and diverse that it is very difficult to identify factors that are influential in any actual combination of factors. To cope with production diseases, it is of high importance to consider the farm-specific conditions, the availability of resources for both farm animals and farm management, and the ongoing outcome of the interactions in various fields. It largely depends on the capability of the farm manager to think through the complexity of the processes on different process levels and to organize appropriate living conditions for farm animals although often facing severe limitations in the availability of relevant resources (labor time, investments, knowledge, etc.).

It can be summarized that in general the enhanced minimum standards fail to clearly improve the animal health status on the farm level in comparison with conventional production that is influenced in the first place by the farm management, being not covered by the regulation on organic livestock.

Product Quality

The milk quality of organic farms compared with their conventional counterparts is a topic of interest for many scientists as well as consumers in Europe and United States. The term 'quality' is documented very diversely in general language use and in the scientific literature. Although some understand something very sound and normal by this term, others consider it as rather something special and extraordinary. According to Mair-Waldburg (2002) quality includes both free of defects and inadequacies and the fulfillment of previously determined properties that exceed the usual. For a consumer-oriented product it is significant that quality includes a high degree of fulfillment of the consumer's expectation as far as the desired properties are concerned.

It is generally accepted that bulk milk SCC are the primary indicator of milk quality in dairy herds and are associated with management practices on the farm (Barkema *et al.*, 1998; Schukken *et al.*, 2003). Based on treatment data from the Norwegian Cattle Health Service, Hardeng and Edge (2001) did not find any significant difference in individual cow SCC between organic and conventional-farmed dairy herds. Other studies show varying results, including better udder health on organic farms (Garmo *et al.*, 2010), no difference (Fall *et al.*, 2008; Zwald *et al.*, 2004; Sato *et al.*, 2005), or even higher levels of mastitis on organic farms (O'Mahony *et al.*, 2006). Thus, the consumer perception that organic milk is of higher quality (Hill and Lynchehaun, 2002) is not supported by scientific studies.

Concerning the meat quality of organic pork and beef, a review revealed substantial variation in the quality of organic meat entering the marketplace (Sundrum, 2010). According to the available literature sources, quality of organic pork and beef provide inconsistent results and often fall short of expectations as it is often similar to that of conventionally

produced meat. Not only in conventional but also in organic meat production, the trade value of carcasses is determined by lean meat and cuts composition in the first place, whereas qualitative traits of meat (e.g., traits of the eating quality) are in general not taken into account. Neither does continuous recording of qualitative traits take place nor is an outstanding meat quality rewarded by higher prices. Of the various parameters, marbling and intramuscular fat, respectively, are highly related to palatability traits in both pork and beef and could be used to distinguish between different levels of eating quality (Sundrum *et al.*, 2011).

Summing up, the expectations of consumers toward a clearly higher level with respect to traits of product and eating quality of organic animal products are in general not met by organic producers, which bring a largely heterogeneous outcome of the production processes onto the market.

Use of Antibiotics

Intensive management practices are closely associated with frequent veterinary usage. For many consumers, and especially those who buy organic food from animal origin, the use of antibiotics in the production process is a matter of concern and a relevant issue of food safety. Indeed, the use of antibiotics includes a certain amount of risk regarding selection and transmission of resistant bacteria (Schwarz *et al.*, 2001) and can promote the development of resistance reservoirs. Therefore, the selection for resistant bacteria is an increasing public health problem. Research has shown increased resistance rates in pathogenic and commensal bacteria of animals related to antibiotic use (Harada and Asai, 2010).

However, antibiotics are a powerful tool to treat animals suffering from infectious bacterial diseases. Because animals should not suffer, allopathic antimicrobials are allowed in the EC Regulation for organic farming. The legislation, however, encourages avoidance of allopathic treatment in organic milk production if any alternative is available and prescribes to a doubling of the withdrawal time on milk and meat compared with conventional herds (EC, 1999). In contrast, the US regulations define any animal treated with antimicrobials as nonorganic for the rest of its life (USDA National Organic Program, 2011). Consequently, the use of antimicrobials has a severe impact on the fate of the treated animal in organic herds. Antimicrobials are therefore only rarely used in US organic herds (Zwald *et al.*, 2004; Pol and Ruegg, 2007). In a questionnaire, administered on site to selected dairy farmers located in Michigan, Minnesota, New York, and Wisconsin, most organic farmers (90.6%) reported no antibiotic treatments of milk cows, whereas 9.4% reported treating 1–10% of milk cows (Zwald *et al.*, 2004).

Information about medication in organic livestock production in Europe is scarce. In Denmark, in a study involving 27 organic and 57 conventional dairy herds, the percentage of cows treated for mastitis per month was 1.8–5.1 (25% and 75% percentiles) in organic herds and 3.3–6.7 in conventional herds (Vaarst and Bennedsgaard, 2002). A study in Switzerland revealed that bacteria in milk from organic dairy cows with mastitis exhibited antibiotic resistance at a comparable frequency as found previously in conventional farms (Busato *et al.*, 2000). In a Norwegian study on conventional and organic farms with respect to udder health and antibiotic resistance in udder pathogens, coagulase-negative staphylococci with penicillin resistance were isolated from subclinically infected quarters in 48.5% of the cases in conventional herds and 46.5% in organic herds (Garmo *et al.*, 2010).

An investigation of the use of antibiotics to fattening pigs in Denmark showed that the conventional herds consumed three times as much as the organic herds (Hegelund *et al.*, 2006). Based on a comprehensive review comparing the health effects of organic and conventional food, Smith-Spangler *et al.* (2012) concluded that the published literature lacks strong evidence that organic foods are significantly safer than conventional foods. According to the authors, consumption of organic foods may reduce exposure to antibiotic-resistant bacteria. Bacterial contamination of retail chicken and pork was common but unrelated to the farming method. However, the risk for isolating bacteria resistant to 3 or more antibiotics was higher in conventional than in organic chicken and pork.

It can be summarized that organic livestock producers use clearly less antibiotics than their conventional counterparts going along with a reduced risk for bacteria resistant to antibiotics.

Inconsistencies between Principles and Minimum Standards

Since 2000, a number of publications have specifically aimed at identifying ethical values or principles of organic farming that can guide practice. Niggli (2000) summarized the ethical values that the pioneers of organic farming referred to as follows: respecting and enhancing production processes in closed cycles; stimulating and enhancing self-regulatory processes through system or habitat diversity; using strictly naturally derived compounds, renewable resources, and physical methods for direct interventions and control; and considering the wider social, ethical, and ecological impacts of farming. Vogt (2000) summarized the main values as a biological understanding of soil fertility, the intensification and maintenance of the agroecosystem with 'biological' and 'ecological' tools, the production of high quality food for a healthy diet, and visions of alternative living and organizing society.

Principles have a normative aim stating what is a 'right' or 'good' organic system. This is comparable to deontological ethics, in which certain principles are formulated to assure respect for a range of fundamental values. Such ethical principles can function both as a source of inspiration and as boundaries for certain activities (Padel *et al.*, 2009). Of particular importance for organic agriculture are the four 'Principles of Organic Agriculture' of International Federation of Organic Agriculture Movements (IFOAM, 2005). The process of formulating core Principles of Organic Agriculture was based on expert and stakeholder consultation, resulting in the Principles of Health, Ecology, Fairness, and Care, democratically accepted by IFOAM's members in 2005. The process aimed to bridge the values from the pioneers of organic agriculture to the present time of globalization and to extended growth of the organic sector. As a result the principles are now considered worldwide as the basis from which organic

agriculture grows and develops. According to Luttikholt (2007), the four principles offer a perspective on how to deal with the challenges of globalization. A response to these challenges seems to be to extend and further detail the standards so that, for instance, externalities can be included. An ideal situation would be in which a balance between the principles and standards can be realized.

However, the previously cited literature reveals a considerable gap between objectives and practices in organic agriculture, particularly in organic livestock production. This gap is discussed below in the Section Principle of Health in relation to the four Principles of Organic Agriculture, providing some examples of inconsistencies without any claim to comprehensiveness.

Principle of Health

> Organic Agriculture should sustain and enhance the health of soil, plant, animal and human as one and indivisible.
>
> –IFOAM, 2005

Although maintaining and enhancing animal health and welfare of an individual animal and of the herd is stated to be an important goal in organic farming (Verhoog *et al.*, 2004), the organic farmers are still far from providing an outstanding health status in comparison with conventional farming. The formulation of a common principle of health, including animal health, has not been done in the past and cannot be expected to change the situation in the future. It could be even argued that such a principle prevents facing the obvious and the reality. Obstacles to reduce the gap are certainly manifold and are expected to vary considerably from farm to farm. As explained above, minimum standards fail to provide an appropriate tool to improve animal health status on the farm level. Thus, the main question is unavoidable, that is, who is to blame in the first place for the current unsatisfactory situation: the individual organic farmers, the standards, the organic associations, the market situations, the consumers, the animal scientists, or the politicians?

Some of the various discrepancies between claim and reality with respect to the handling of the animal health issue in organic and conventional livestock production and some of the conflicting areas provoked therewith have been previously addressed by Sundrum *et al.* (2011). According to his analysis, all stakeholders are involved in the current unsatisfying health status on organic farms and are more or less responsible. Producers and retailers claim to offer products that derive from healthy animals without providing transparency and evidence of the animal health status of farm animals. Retailers want to increase the turnover by offering organic food with comparably low prices at the expense of the possibilities of the farmers to investigate in substantial improvements of animal health. Producers who strive for a high status of animal health by using appropriate management concepts and encountering higher production costs are confronted with unfair competition when competing with their products on the same market as those who produce on a low-cost and low-quality base. A high percentage of consumers announce their special interest in the issue of animal health and their willingness to pay premium prices but hesitate to do so when corresponding food is offered and instead prefer purchasing cheaper food. Many consumers prefer to delegate responsibility for ethical issues when choosing animal products to the retailer or the government and are by their ignorance jointly responsible for the severe deficits in animal health within livestock production.

Owing to the complexity of the interactions of various factors on different scales, evidence cannot refer to some input variables, for example, minimum standards. The farm-specific animal health status is the result of the steering process of the farm management and hence the emergent property of the farm system. Correspondingly, to improve the animal health status, the farm management has to focus on the outcome of the production process. Appropriate reference points for an output orientation are, for instance, the prevalence rates of production diseases on the individual farm. Within a label program such as organic, quality assurance, and control programs for products labeled as deriving from healthy herds should rely on fixed levels regarding an acceptable prevalence rate of diseases.

Despite decades of research and an enormous increase in knowledge, the prevalence and incidence rates of production diseases remain high, independent of the production method (LeBlanc, 2013). The reasonable assumption that the situation might have been worse without the elaborated knowledge in animal science is not convincing. In fact, it is not known very much about the impacts of animal science on the status of animal health. It could also be argued that the problems are induced to some degree by specific disciplines of animal science whereas other disciplines fail to provide appropriate tools and knowledge to compensate for suboptimal living conditions in practice and for growing demands on the regulatory capacities of farm animals in connection with increasing performance levels.

The fact that there is an increasing gap between the availability of specific knowledge and a target-aimed implementation of knowledge into practice should no longer be masked. It can be partly explained economically by higher preventive costs in relation to failure costs in many farm situations (Hogeveen, 2012). However, the gap is also due to the fact that the implementation of measures often fails to be effective because the effectiveness depends to a high degree on the specific farm context, which is often not or only partly considered in research work. Farmers are often left alone in their need to decide which measures are likely to be effective and efficient in their specific farm situation.

In addition, the standards themselves are inconsistent and provoke conflicting aims. For instance, although diseased animals should be treated immediately when showing clinical signs to prevent suffering, the use of antibiotics and chemically synthesized remedies is restricted (in Europe) or totally banned (in the United States). The farmer is at risk to lose the premium for organic products when treating animals with chemically synthesized remedies, which they may try to avoid. Correspondingly, farmers often decide, not to treat diseased animals at all or shift to phytotherapeutic and homeopathic remedies. These remedies, however, often lack an effective therapeutic effect for the diseases and the condition for which the treatment is intended. For the certification bodies it is nearly impossible to verify that animals should have been

treated appropriately as long as the incidence and prevalence rates of production diseases are not a control point for the certification bodies. Thus, the high incidence and prevalence rates of production diseases in organic livestock production are not only the result of suboptimal living conditions and farm management but also the consequences of inappropriate and unsuccessful treatments.

Principle of Ecology

> Organic Agriculture should be based on living ecological systems and cycles, work with them, emulate them and help sustain them.
> –IFOAM, 2005

Ecosystems are defined as a community of living organisms (plants, animals, and microbes) in conjunction with the abiotic components of their environment, interacting as a system (Chapin *et al.*, 2002). Biotic and abiotic components are linked together through nutrient cycles and energy flows.

Producers (plants), primary (herbivores) and secondary (carnivores) consumers, and decomposers and detrivores are a maintaining part of dynamic equilibrium in the matter and energy cycle. The sustainability of matter and energy cycles in the ecosystems is based on self-regulatory processes. It is often emphasized by proponents of organic agriculture that organic farm systems should enhance production processes in nearly closed nutrient cycles while stimulating and enhancing self-regulatory processes. These considerations neglect that ecosystems in general produce a comparably low biomass and are not compatible with the goal to produce high amounts of biomass that is exported from the systems, this being the case in farm practice in terms of products.

In farm systems at least the nutrients that are lost due to the purchased products or due to emissions and the conversion losses have to be substituted by external sources. To minimize the need for nutrient inputs, the farm manager has to gain detailed knowledge on the input and output variables. According to Liebig's Law of the Minimum, valid for both plant and livestock production, growth processes are controlled not by the total amount of resources available but by the scarcest resource. When striving for an enhanced productivity in organic farming, the farmer should be aware of those first limiting factors to be able to substitute where necessary in order to increase the efficiency in the resources. Correspondingly, organic farms are not equivalent to a self-regulatory ecosystem. As an agroecosystem, organic farms require a stewardship, able to steer the nutrient flow through the various subsystems of the farm system and to deal among others with the restricted availability of resources (nutrients, labor, and investments).

Farm animals react very sensitively to a restricted availability of limiting nutrient factors. A suboptimal nutrient supply is often the cause, not only of metabolic disorders but also of infectious diseases deriving from a suppressed immune competence due to an imbalanced nutrient supply. To close the nutrient cycle of an organic farm in terms of minimizing the nutrient input should not be a goal in itself as it can contradict with the principle of animal health, which requires a balanced nutrient supply and a farm management that is capable of providing this in an appropriate manner for all farm animals in their various stages of life. On-farm assessments show that many farmers are not able to correspond to this demand (Sundrum *et al.*, 2008). In dairy production, farmers are challenged and have difficulties to provide an appropriate energy supply due to a lack in the availability of energy-rich forage, such as maize silage and fodder beets, as well as restrictions in the use of concentrate.

In the case of monogastric animals, the first limitation in exploiting the genetic potential of monogastric animals in organic farming is the supply of limited amino acids (Sundrum *et al.*, 2006; Høøk Presto *et al.*, 2007). As soybean meal from conventional processing and synthetic amino acids are banned as feed ingredients, grain legumes represent the main protein source. These are characterized by comparably low concentrations of limited amino acids. The preferred use of homegrown versus bought-in feedstuffs can cause a high variation in the nutrient content of feeding rations and this has consequences for the growth processes within the different stages of life, for the performance level, and the occurrence of imbalances and metabolic disturbances. Restrictions in the availability of ingredients do not necessarily give rise to specific nutrient deficiencies, provided that careful ingredient control, ration formulation, and mixing of feed are carried out.

A recent study on the level of nutrient efficiency in comparison between organic and conventional dairy cows revealed that the overall farm efficiency of N use (animal product N per N input) did not differ significantly between conventional and organic farms, neither in relation to the total farm nor with respect to defined subsystems but showed a large variability between farms (Sundrum and Suender, 2012). The results provided farm-specific pictures, indicating adjusting screws that suggest the most effective and efficient measures on how to increase N efficiency. Differences between farms and subsystems indicated considerable potentials for improvements without adverse effects on production. Thus, striving for nutrient efficiency provides options to balance ecological and economic goals. However, improvements cannot be expected by following general objectives or recommendations but require farm-specific assessments and regulation processes based on the availability of comprehensive data.

Principle of Fairness

> Organic Agriculture should build on relationships that ensure fairness with regard to the common environment and life opportunities.
> –IFOAM, 2005

Positive cost–benefit calculations of recommended measures are essential to convince the farmer into action. Neither the formulation of principles nor profound knowledge alone can be expected to provide progress and improvements if farmers do not gain any benefit and profit from the market to compensate for the additional efforts and resources needed to improve the farm management aiming at product and process qualities. Currently, producers are very much at the mercy of retailers and supermarkets in terms of price paid, for example, per liter of milk or kilogram of carcass meat. In the past, retailers had continuously tried to drop the prices to producers,

therewith widely ignoring the impacts on producers and farm animals. As a consequence, dairy farmers have been chronically underpaid in recent years and left alone by the market, which does not offer any monetary incentives to substantially improve traits of product and process qualities on the farms. Thus, the market fails in improving traits of product and process quality.

Although the labeling of organic products by regulations was introduced to prevent misuse and unfair competition, the current market conditions widely ignore the large variability in the quality traits and in the impacts on common goods, promoting unfair competition when enabling equal prices for very different performances in relation to product and process qualities. Farmers who gain economic benefits by selling products while providing only a low-quality level undermine any efforts of other farmers attempting to improve quality traits (Sundrum, 2007a). Producers who strive for product and process qualities by making use of appropriate management concepts and encountering higher production costs due to increased efforts and resources to be used are confronted with competitive disadvantage and unfair competition when competing with their products on the same markets and with the same prices as those who produce on a low-cost and low-quality base, while hazarding the consequences. Consequently, for example, dairy cows pay the gap between a continuous increase in productivity and milk yield and the restricted availability of various resources by the farm management among others with an increase in the prevalence rates of production diseases and with a decrease in longevity (Knaus, 2009).

Despite the fact that many consumers express their wishes for high milk or meat quality, the payment and marketing systems counteract all efforts to follow consumer demands and to enable a product offer with differentiated eating quality. It is concluded that only a direct assessment of qualitative traits and a payment systems that honors quality grades beyond average can contribute to improve the currently unsatisfactory situation. Without evidence-based progress and a system of financial penalties and bonus payments to promote top quality, organic livestock production faces the risk of losing consumers' confidence while being trapped between own demands, consumer expectations, and limited resources (Sundrum, 2008).

Principle of Care

> Organic Agriculture should be managed in a precautionary and responsible manner to protect the health and wellbeing of current and future generations and the environment.
>
> –IFOAM, 2005

Although organic agriculture and organic livestock production strives for self-sufficiency, at least for a low input farming, it makes considerably less use of external nonrenewable resources and in general can be expected to have less negative impacts on the environment. Therefore, it can be assumed as being more sustainable than comparable intensified conventional farm systems. However, the principle of care in its current description seems to be overambitious. It is not convincing to express some kind of responsibility for future human generations while in the current farm practices many organic farmers are not able to protect the health and wellbeing of the farm animals for which they are directly responsible. The high prevalence and incidence rates of production diseases in organic livestock farming indicate that farmers often fail to care and deal with the farm animals appropriately. Production diseases are multivariate responses to a complex set of interrelated causal factors and are often due to mistakes of the farmer, inadequate handling, and inappropriate housing conditions (Enevoldsen and Gröhn, 1996). In different studies, organic dairy producers were more likely to use less outside support from experts and advice from veterinarians for recommendations of treatment than conventional producers and were more likely to rely on advice from other farmers (Zwald *et al.*, 2004; Richert *et al.*, 2013b).

Furthermore, it is not in correspondence with a principle of care to sell organic products that derive from diseased farm animals. For instance, a high level of SCC in milk indicates that cows suffer from a clinical or subclinical mastitis. The threshold differentiating infected and noninfected mammary glands was found to be greater than 200,000 cells/ml on the animal level by the IDF (1999), whereas the majority of organic dairy farms exceed this threshold in the milk of the bulk tank containing a mixture of all lactating cows on the farm. Although milk with a high somatic cell count is not a direct issue of food safety, due to the fact that milk has to be pasteurized by which the pathogens are killed, the high SCC above the threshold found in milk from organic and conventional cows cannot pass through as an expression of care neither toward dairy cows nor toward consumers.

Conclusions

Although the options to execute species-specific behavior pattern are clearly improved for organic farm animals, the enhanced level of minimum standards in organic livestock production failed to entail a clearly improved animal health status and a higher product quality in comparison with conventional production. The reasons for these unsatisfying findings are manifold as are the influencing factors within and between individual farms. The large heterogeneity between organic farms in their structures, local conditions, availabilities of resources, living conditions for the farm animals, and last but not least skills of the farm management corresponds with the heterogeneity of the outcomes of the production processes in terms of product and process qualities.

A further enhancement of minimum standards cannot be expected to improve the situation due to the general inappropriateness of this approach in livestock production. In the current situation, organic agriculture is far from providing the best solutions for different regional, national, or global challenges. However, without the fact that organic livestock production was able so far to establish itself as an economically viable production method – although being only a niche production – and without being recognized by an increasing number of consumers and retailers, and hence by politicians and also finally by traditional agricultural scientists, the option to overlook the agricultural scenery and the ongoing developments from a different perspective would still be

missed, identifying possible benefits and progress but also being aware of constraints.

Not only organic but also conventional livestock farming fails to improve animal health status and traits of product quality. Both production methods should learn from the field experiment of organic farming – from their success in various fields as well as from their failures in achieving certain aims – and should try not to repeat misguiding tracks. However, when recognizing the current attempts of conventional farming to restore its spoilt image by initiatives with specific label programs based on minimum standards, there is little hope that this will happen in due time.

Retrospectively, it can be argued that it was a failure from the beginning of labeling organic products to make the production method an identifying criterion for labeling organic food. What might more or less work for organic plant products does not work for livestock production. Although organic agriculture has been developed and still is dominated by specialists with a focus on plant cultivation, the specific requirements of farm animals were not considered when the course of organic agriculture was set in the middle of the last century. It has proven to be a fundamental false estimation when transferring suppositions with respect to plants being primary producers within an agroecosystem to farm animals as primary consumers of plant biomass. Self-regulating processes within farm animals are far more complex than those in plants while at the same time huge differences exist between individual animals and their specific demands, requiring the necessity for the farm management to regulate the living conditions and provide a nutrient supply according to the individual requirements and needs of farm animals.

Although minimum standards do not have a resounding success on animal health status and the level of product quality, the situation is complicated by the fact that farmers face a severe limited availability of resources, such as high quality feed, labor time, or investments within the farm system and simultaneously a high pressure on the production costs. Not only conventional but also organic livestock production is characterized by a buyer's market where the retailers are pressing the producers for the lowest purchase price, therewith widely ignoring the internal and external effects of this strategy. Because the prices for conventional products are already on a low level, premiums for organic products are often not sufficient to cover the additional production costs so that organic farmers are liable to be trapped between aroused consumer expectations and limited resources.

Currently, organic agriculture cannot claim to promote a sustainable development, neither for the farm animals and organic farmers nor for the production method of organic agriculture. Lack of success in criteria of animal health and product quality being very important for the buying decisions of consumers calls for drastic changes and not only for slight modifications if the credibility of organic agriculture should be prevented from further erosions, depriving the production method of their commercial basis.

An essential precondition to improve the current situation is marketing conditions that honor the production of products with a high level of product and process quality instead of focusing alone on quantitative traits and low prices. Appropriate prices and monetary incentives for a qualitative production are the starting conditions for farmers to provide appropriate living conditions, intensive care, and adequate treatments so that diseased animals would occur as exceptions and not as the rule as it is nowadays. Only appropriate living conditions enable the farm animals to adapt and cope with their environment and ongoing changes and to keep themselves healthy.

The previous approach of minimum standards is doomed to fail, among others, because it provides a large variation of the outcome in terms of traits of product and process quality; it provokes unfair competition and therewith torpedoes any efforts to invest monetary and labor resources into improvements while allowing retailers to play their game in playing off the producers against one another.

In urgent need of more transparency, it is concluded that only a shift in the paradigm from a standard- and input-oriented to an output-oriented production process is able to overcome the inconsistencies regarding the current organic principles and the main constraints in organic livestock production. Verifiable information about the level of product and process qualities emerging from the production process within each farm system has to be provided by the producers. Simultaneously, a high level of product and process quality has to be honored by premium prices to cover the additional costs and efforts that are needed to improve quality production. The output-oriented approach has to be accompanied and supported by a systemic approach. It is beyond the scope of this article to explain this approach comprehensively. The potentials of this approach for livestock production are introduced elsewhere (Sundrum, 2007b; 2010; 2012b).

Although neoclassical economists and the majority of agricultural scientists pretend to have confidence in the ability of markets to drive technological and behavioral changes that will enable the capacity of the economy–environment system to satisfy the increasing needs, ecological scientists tend to believe that solving problems in relation to restrictions in the availability of resources cannot be left to technological developments and economic growth alone but will require different kinds of regulations in a top–down as well as a bottom–up approach.

Glossary

Buffer zone An area surrounding or adjacent to an area for production of plants in a certification scheme designed to minimize the probability of spread of the target pathogens, pollen, or seed into or out of the block, to meet phytosanitary or other control measures as defined in a certification standard.

Certification standard Comprehensive process established and authorized by a regulatory entity for the production of plants free of regulated pathogens, with predefined trueness-to-type or genetic purity. These regulations also define plant production, plant identification and labeling, and quality assurance requirements.

Generation or G-level It indicates the relationship of plants in a certification scheme to the original pathogen-tested plant material at the top of the scheme. Regulations developed by certifying agencies specify the conditions under which each Generation (G) level must be maintained in order to meet the standard.

Heat therapy A method used to eliminate viruses in which plants are grown at 37–40 °C for 4–6 weeks. After this meristem tips (0.3–1.0 mm) are removed and used to regenerate plants. This results in the production of plants that are often free of targeted pathogens. Once grown in tissue culture, rooted and planted in soil, the plants are retested for the targeted pathogens to determine their health status.

Index Procedure to determine whether a given plant is infected by a targeted pathogen. It involves the transfer of a bud, scion, sap, etc. from one plant to one or more indicator plants sensitive to the virus.

International Standard for Phytosanitary Measures It is an international standard adopted by the Conference of the Food & Agriculture Organization(FAO) of the United Nations, the Interim Commission on Phytosanitary Measures, or the Commission on Phytosanitary Measures, established under the International Plant Protection Convention.

Meristem-tip (tissue) culture A pathogen-elimination technique whereby tissue pieces (cells) are separated from an organism and cultured in a sterile growth media apart from that organism. One of the preferred pathogen-elimination methods for plants is 'microshoot tip culture,' which is effective for eliminating most viral, bacterial, and fungal contaminants. In this technique a meristem tip of less than 0.3–1.0 mm is extracted from the shoot and placed in sterile tissue culture growth media; the meristem then grows to a complete plant.

Phytosanitary measure Any legislation, regulation, or official procedure with the purpose to prevent the introduction or spread of pests or diseases.

Quarantine Official confinement of regulated articles for observation and research or for further inspection, testing, and treatment.

Vegetative propagation Plants are reproduced using the following methods: cuttings, layering, division, grafting, budding, and tissue culture.

Introduction

Large-scale production and globalization of agriculture has resulted in a narrow germplasm base for all major food crops being grown over vast areas, which increases the risk of epidemics that could impact food security on a broad scale (Strange and Scott, 2005). In addition, the majority of the production of these crops is in areas far from their centers of origin and subjected to many plant pathogens that they did not coevolve with. Cassava is an excellent example of this, as its center of origin is in South America, but African cassava mosaic virus, which causes a devastating disease in Africa, is not present in South America (Fauquet and Fargette, 1990; Thresh *et al.*, 1998). Most of the production of these crops is isolated from new strains of pathogens as they evolve at centers of origin and are at risk of severe disease outbreaks should new strains of a pathogen be distributed with planting material. This is also true for most of the fruit, vegetable, and

 doi:10.1016/B978-0-444-52512-3.00173-X

ornamental species that are grown commercially. Concomitant with the globalization of crop plants is an increased risk of globalization of plant pathogens that can lead to serious epidemics. The classic example of such movement of a pathogen is *Phytophthora infestans*, the causal agent of potato late blight in the mid-nineteenth century, where its impact on human suffering and migration is well documented (Schumann, 1991). Yet, 150 years later, new strains of this pathogen have emerged and continue to cause serious plant disease problems (Vleeshouwers *et al.*, 2011). There are examples of outbreaks of all types of pathogens (fungi, bacteria, nematodes, and viruses) that have resulted from movement of plant pathogens with the movement of plant propagation material.

To protect agricultural production from introduced pathogens, two types of phytosanitary systems have been employed. Plant quarantine is generally used at the national level to restrict introduction of plant pathogens that are not present in a country or have limited distribution and active programs to eradicate or delimit the pathogen. There are also domestic quarantines that restrict the movement of plant material within a country to address pests and pathogens that have limited distribution or may have been deregulated as a federal quarantine pest. Plum pox virus (PPV), Golden nematode, Light brown apple moth, *Ralstonia solanacearum* race 3 biovar 2, and *Phytophthora ramorum* are examples of quarantine pathogens and pests in the United States. Certification programs are national, state, or provincial programs used to produce planting materials, vegetative or seed, that are free of or have less than some predetermined threshold of various pathogens (Waterworth, 1998). These programs primarily target domestic pathogens for plants at the G1–G4 (**Figure 1**) level of certification programs. These programs aim to ensure that the planted crop has a pathogen(s) level low enough to minimize the risk of severe crop loss, increasing the chance of harvesting an acceptable crop. The pathogen tolerances allowed in certified plants depends on the pathogen, crop, and agroecosystem where the crop is grown. The primary goal of quarantine and certification programs is to facilitate movement of plants without increasing trade of plant pathogens. The objective of all plant certification programs is to provide a supply of healthy plants, which is accomplished through adherence to Best Management Practices (BMPs) that are science based together with a defined level of testing to monitor the effectiveness of the program. The application of BMPs to the production system combined with audit testing has proven to be a very useful means of producing plants of high health status. Certification programs should be reevaluated periodically to take into account new pathogens or vectors that have been reported in the region, or other changes that affect the pathogen, vector, host, or environment that may impact the integrity of a certification scheme.

BMPs require that a Hazard Analysis and Critical Control Points evaluation of the entire certification system be completed. This process is used to: (1) identify weak points and greatest risk factors to the system in terms of introduction of pathogens or pests, and (2) establish inspection, testing and mitigation procedures, and record-keeping requirements (Parke and Grünwald, 2012). Once the weak points are identified, management practices are designed to prevent intrusion of pests and pathogens. Mesh size on a screenhouse might be adjusted to account for the primary virus vectors in the region to protect a G1 block. For example, if pathogens in a region are vectored by aphids the screen size might be larger than in another region with pathogens vectored by thrips. Vector management in field blocks of certified plants will be adjusted based on the vectors and pathogens present in the region. Knowledge of the phenology of vectors is also important, because times of peak vector movement present the greatest risk of pathogen intrusion into the system; thus, vector control measures may well change during the year to take into account the risk of vector migration into a nursery. Knowing which of the targeted pathogens are most prevalent in a region and how they are vectored are important considerations when developing BMPs for a nursery (Martin and Tzanetakis, 2013).

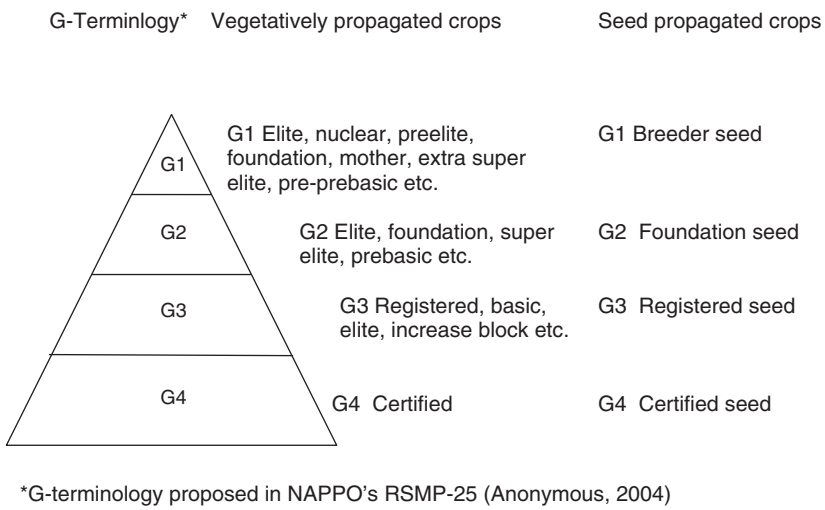

Figure 1 Simplicity of the G-terminology and the concept of G-levels for identifying the stages of plant propagation in certification programs for phytosanitary purposes.

Quarantine

In addition to certification programs that are designed for mass production of planting materials of high health status for plant, food, and fiber production, there are extensive quarantine programs that have been developed in many countries to reduce the risk of introduction of exotic pests. Though not the focus of this article, quarantine goes hand-in-hand with certification to provide an integrated system to protect agriculture and environment from plant pests and pathogens, thus its relation to certification will be touched on briefly. The rationale for a brief overview of quarantine is that many certification programs focus on domestic or endemic pathogens, with the assumption that quarantine pathogens are detected and eliminated at the stage where plants enter the country and need not be included in the domestic certification program. Quarantine programs are operated primarily at the national level and deal with pathogens that are not known to occur in the country or are present at a very restricted level and have active programs targeted to eradicate or prevent further spread of the pest or pathogen (Foster and Hadidi, 1998; Reed and Foster, 2011; Anonymous, 2006). As examples, plant material of berry crops, citrus, grape, potato, sweet potato, pome, and stone fruit, etc. coming into the United States under quarantine are tested for exotic pathogens before they are released for propagation, but they could be released if found to be infected only with viruses already endemic in the country. In some cases plants may be held in quarantine for 3–4 years while graft indexing on indicators is carried out.

To be effective, quarantine programs are dependent on the public understanding the risks associated with introducing exotic pathogens into natural and agricultural ecosystems. Public in this sense includes anyone who may wish to transport plant material from a foreign country to their homeland, including hobbyist interested in a new ornamental or food crop to add to their garden or plant collection, plant breeders interested in new potential germplasm, plant pathologists interested in adding to their pathogen collection for scientific study, germplasm curators attempting to broaden the diversity of their collections, or growers interested in getting a head start on a new cultivar developed in a foreign country. Also, an effective quarantine program needs to have an effective and efficient mechanism to introduce plant material into the country. This combination of an educated public that understands the risks of introducing foreign pathogens and pests, together with an efficient system to bring plant material through approved quarantine and testing facilities will reduce the temptation by individuals to do 'suitcase' imports that could threaten local environments and agriculture. The introduction of PPV into Pennsylvania highlights the benefits of quarantine systems to exclude exotic pathogens. Plum pox is a devastating disease first identified in the early 1900s in Bulgaria that has since spread through much of Europe and the Mediterranean countries, where it is the most serious disease of stone fruits. It was detected for the first time in the Western Hemisphere in Chile in 1994 (Herrera *et al.*, 1998) and is now considered to be widespread there and has since been detected in Argentina. PPV was detected in a localized area of Pennsylvania in the United States in 1998 (Levy *et al.*, 2000) and an eradication program was implemented immediately. After 14 years, the eradication effort was deemed successful, but the cost was in excess of $55 million US dollars to eliminate the pathogen from a relatively small geographic area (Welliver, 2012). Thus, quarantine programs can be an effective and economical way to reduce international movement of plant pathogens and pests to protect local agriculture and native flora.

The International Plant Protection Convention (IPPC) is an international agreement on plant health to which 181 countries are signatories. The Secretariat of the IPPC is provided by the Food and Agricultural Organization of the United Nations. The IPPC has the mission to protect cultivated and wild plants by preventing the introduction and spread of pests and pathogens. They develop standards (International Standards for Phytosanitary Measures (ISPMs)) that are recognized by participating countries and provide for science-based standards for the safe movement of plants and plant products. As an example, ISMP No. 28 (Anonymous, 2007b) provides recognized standard treatments to eliminate plant pathogens and pests, including fumigation, cold treatment, heat treatment, and irradiation; and ISMP No. 31 (Anonymous, 2008) provides agreed on sampling levels that participating countries use when shipping plants or plant products internationally to protect against movement of quarantine pests and pathogens. The IPPC develops standards for range of issues related to plant protection. Once the standards are approved by the IPPC member countries, they become an ISMP.

Certification

Certification programs have been developed for many vegetatively propagated food crops over the past 50 years (Hadidi *et al.*, 1998; Hadidi *et al.*, 2011). The first certification programs were developed in The Netherlands and Germany in the early 1900s for potato production when they realized that leaf crinkling, rolling, and mosaics were transmitted through the tubers to the next generation and that by selecting the most vigorous and healthy-looking plants for propagation, tuber production was improved greatly. They developed a program for plant inspection and production, which was adopted in the United States and other countries long before it was known that many of the diseases were caused by viruses. In the United States and Canada the first seed potato production programs were established in 1913 (Slack and Singh, 1998). Visual inspections still play a major part in seed potato certification programs with inspections carried out early and midlate in the growing season to observe foliar symptoms, at harvest for observing tubers symptoms, and a postharvest inspection of plants grown from tubers to look for late-season infections (Frost *et al.*, 2013). Visual inspections are part of all plant certification programs. Trained inspectors also watch for other problems, such as herbicide damage, cultivar mixtures or trueness-to-type issues, physiological disorders, etc. During visual inspections, thousands of plants can be observed in a relatively short time. In most programs there is also laboratory testing that is carried out on each tuber or 'seed' lot to identify viruses that may be present and to monitor for symptomless pathogens. As laboratory-based diagnostics are improved in terms of sensitivity, specificity, and costs, more programs are

incorporating their use to improve the quality of the program. Certification programs have been developed for a wide range of crops (Hadidi *et al.*, 1998). Testing methods including mechanical transmission to herbaceous hosts, immunological and molecular techniques (Enzyme-linked immunocapture assay (ELISA), Polymerase chain reaction (PCR), etc.), isolation of fungi or bacteria, etc. that are used for detection of various pathogens are similar in all programs. With woody crops there is often the need to do graft transmission onto indicator plants to test for uncharacterized graft-transmissible agents (Converse, 1987; Hadidi *et al.*, 2011).

There are many definitions for certification programs. North American Plant Protection Organization (NAPPO) defines a certification program as: "A domestic program consisting of maintenance, multiplication, distribution, and production of plant materials intended for release either domestically or for export, under an officially sponsored certificate attesting to the status of the material" (Lanterman *et al.*, 1996). Many certification programs are based on a published standard that defines site selection and preparation, isolation distances from plants of the same species and other vegetation, number of inspections, record keeping on plant traceability so that tracebacks or traceforwards can be done if a problem should arise, a pest and disease management plan, records of all pest management activities, the conditions and protocols to be followed during plant or seed production, and types and amount of testing that needs to be done at each level in the propagation cycle. The selection of plant material that is true-to-type is an essential first step. The selected plant(s) is then subjected to pathogen testing using a range of laboratory and biological indexing. If infected with any of the targeted pathogens listed in the standard, the plants are subjected to 'cleanup.' After 'cleanup' the plants are retested to ensure the pathogen(s) have been eliminated. Once determined to be free of targeted pathogens and true-to-type, this plant can be designated as a G1 (**Figure 1**) plant that enters into the certification program. In many cases these plants are maintained in protected culture (screenhouse) and become the source plants that are propagated in certification programs.

There is an effort in the United States to develop audit-based certification programs that rely on BMPs outlined in the Certification Standard (Thompson, 2011). An audit-based program relies on compliance monitoring and requires a reasonable level of trust between the regulatory agency (inspectors) and nursery managers for the certification systems to function. The audit or inspection assesses the degree of compliance of the nursery to the certification standard, so that plants can be certified to meet that standard. An auditor or inspector designated by the certifying agency is responsible for the audit process. All records of the nursery can be reviewed by the auditor (Thompson, 2011). With such a system in place, record keeping by the nursery becomes even more critical as the inspector's decision will be based on the records reviewed, visual inspection of the nursery, and some limited testing. The goal is to have a systems approach that uses science BMPs for nursery production of plant materials (Parke and Grünwald, 2012).

The use of pathogen-tested planting material is the first and arguably the most important step for the control of many systemic plant pathogens. Most effort in this area has focused on viruses, viroids, systemic bacteria, and phytoplasmas because there are no postinfection treatments that can be used in plant or food production systems to rid plants of these pathogens. Many important systemic pathogens are not transmitted through the seed or transmitted to less than 100% of the seedlings, or transmitted as seed coat contaminants that can be controlled with various seed treatment methods (Ling, 2010; Liu *et al.*, 2014). In this case, seedlings free of the targeted pathogen(s) can be identified and then grown in isolation to produce seed free of these pathogens or with an incidence below some predetermined threshold. With seed coat contaminants the seed can be treated to inactivate pathogens on the seed surface (Ling, 2010). In the case of vegetatively propagated crops it is often necessary to eliminate a specific pathogen, usually through thermal-, cryo-, or chemotherapy combined with meristem-tip culture to produce plants free of the targeted pathogens (Mink *et al.*, 1998; Laimer and Barba, 2011). The plants regenerated from such meristems are then thoroughly tested, and a single plant free of pathogens of interest is the starting point for massive vegetative propagation. In the case of seed or vegetatively propagated plants, the plants are propagated under a defined set of conditions described in a certification standard.

Certification standards often have tolerance levels of some small percentage of infection, defined requirements for the site where the crop (seed or vegetative) is grown, required field inspection(s) during the production cycle that include cleanliness in terms of weeds, other crops that may serve as contaminants in seed lots or as hosts for targeted pathogens and freedom from pathogen vectors. Tolerances for pathogens depend on the rate of pathogen spread for annual crops, but tolerances are much lower for perennial crops. Crops that are only grown for a single year or a few years in production fields, such as most seed crops and potatoes, strawberries, sweet potatoes etc., may have higher tolerances than most of the fruit and nut crops, such as citrus, tree fruits, grapevines, or berries, which are expected to be productive for many years or decades in the same field. To set tolerances for various pathogens requires sampling and testing, and a major concern is how many samples to test. The number of samples that need to be tested per lot to achieve a confidence level (i.e., 95% or 99%) that a pathogen is not present is outlined in ISPM No. 31 (Anonymous, 2008). In some countries, certification schemes are managed at the national level and in others at the state or provincial level.

Vegetatively Propagated Crops

Plant pathogens are recognized as major constraints to agriculture production worldwide. Most fruit and nut crops; major food crops such as potato, cassava, sweet potatoes; and many ornamentals are vegetatively propagated, using cuttings, tubers, or rhizomes. More recently, tissue culture propagation has become a major component of mass propagation for many of these crops. Elaborate protocols are used to eliminate targeted pathogens from one or a few infected plants to provide a source of plant material free of these pathogens (Mink *et al.*, 1998; Laimer and Barba, 2011). Plants entering a certification program are often advanced selections, cultivars, or varieties

developed in breeding programs. In some cases breeders work closely with the cleanup programs and get plants into the testing and cleanup phase before cultivar release, in an effort to have certified plants available at the time of release. Another source of material entering certification programs are 'heritage' cultivars – cultivars that have not been used for many years but are maintained at germplasm repositories. As requests for these cultivars have increased, there is a need to confirm that they meet current certification standards before commercial nurseries are willing to add them to their production systems. In the United States, there is an effort to have new cultivars coming into the country, as well as those developed in-country go through one of the 'clean plant centers' that have been developed over the past 50 years. Increased funding for these programs at the federal level since 2009 has provided for capacity building and the ability to process materials in a more timely manner to meet the needs for food production. These plants are tested for target pathogens before they enter into a G1 block, then a certification program and made available for production. In many cases, the G1 block is maintained by federal, provincial, or state government agencies, or some type of government/private entity, though recently private companies are maintaining their own proprietary G1 germplasm. These plants are tested on a predetermined schedule to monitor for reinfection, in addition, these blocks are retested if a new virus is discovered in the crop that may have been missed with the testing procedures used previously.

Producing G1 Plants

1. Candidate plant (advanced selections, heritage, new, or imported cultivars) arrive at clean plant center, (time = 0, T = 0).
2. Testing program to determine the health status of the plants with respect to targeted pathogens listed in the certification standard, grafting for many fruit and nut crops. This process can take up to three years for crops, such as grapevines or fruit trees, but less time for other crops (T = 0.2–3 years). If no grafting is required this can be completed in several weeks; this is the case for some crops, such as potatoes.
3. If negative for all targeted pathogens, the plant enters the G1 block. If infected, the plants are put through therapy treatment (2–6 months), meristem-tip cultured and whole plants regenerated (3–12 months).
4. These plants are then retested and, if 'clean,' enter the G1 block; but if still positive they go through the therapy again (T = 0.1–3 years). This is repeated until 'clean' plants are obtained. Each cycle of testing can take up to 3–4years for crops like grapevines or fruit trees, 1–2 years for strawberry or *Rubus*. In most cases protocols have been developed such that there is a reasonable likelihood of having 'clean' plants after the initial cycle of therapy. However, if three cycles of cleanup were needed to get plants free of targeted pathogens this can easily require 6–12 years, depending on the crop.

There is a misconception among many growers and researchers that 'tissue culture' propagated is synonymous with virus free. This is not the case. To eliminate viruses it is necessary to regenerate plants from meristematic tip, generally less than 0.5 mm and often in combination with some type of therapy (thermal, cryo, or chemo) before removing meristems (Mink *et al.*, 1998). Some viruses move into the meristematic tissue quite effectively, and a combination of thermal therapy or chemotherapy are required to get meristematic tissue free of the virus (Chen and Sherwood, 1991). In the past these were referred to as 'heat stable' viruses and were 'difficult' to eliminate using thermal therapy and meristem-tip culture, whereas 'heat labile' viruses were much easier to eliminate. One now know that many of the 'heat labile' viruses are phloem-associated viruses, such as luteoviruses and closteroviruses, and the reason they are 'heat labile' is that the phloem tissue is not differentiated in the meristematic dome. Thus, the virus does not move readily into the meristem. This is the case for the Grapevine leafroll-associated viruses, which are in the *Closteroviridae* family. In raspberry, Raspberry leaf mottle and Raspberry leaf spot were considered 'heat labile' as they were relatively easy to eliminate. These two diseases are caused by strains of Raspberry leaf mottle virus, which is a Closterovirus and phloem limited. Raspberry bushy dwarf virus (RBDV) was considered a 'heat stable' virus because it is difficult to eliminate using thermal therapy and meristem-tip culture. RBDV infects most cell types and is not restricted to phloem tissue, thus, it likely moves into the meristematic dome much sooner than phloem-restricted viruses. The ease of obtaining meristems free of a virus in combination with heat therapy is not related to the heat stability of the virus, but rather how rapidly or effectively it can invade the meristematic tissues.

The 'cleanedup' G1 plants are maintained under clearly defined conditions to minimize the risk of reinfection and should be free of all targeted pathogens outlined in the certification standard. In many cases the G1 plants are maintained in protected culture, such as in a screenhouse. The G1 plants are then sold to private nurseries for mass propagation under a set of conditions outlined in a certification program that is managed by a regulatory agency. The goal is to have a systems-based approach that addresses risks of reinfection and pathogen spread during plant propagation.

There are multiple cycles of plant increase for vegetatively propagated crops and unfortunately a wide range of terms have been used to identify each cycle (**Figure 1**). In 2004, the NAPPO (RSMP no. 25; Anonymous, 2004) suggested the use of a simple terminology for the cycles of vegetative propagation. G1 plants are the plants that have tested negative for all targeted pathogens outlined in the certification scheme. G1 plants propagated by tissue culture or by traditional vegetative propagation methods become G2 plants, and multiple cycles of tissue culture can be carried out and still retain G2 status. The use of tissue-culture propagation and the number of propagation cycles allowed in tissue culture should be defined in the certification standard and will vary depending on the crop and certifying agency. G3 plants are derived from G1 or G2 plants. G4 plants are grown as potted plants that are propagated from G1, G2, or G3 plants and grown at another location. Most existing programs use the various terminologies shown in **Figure 1**, but follow this basic scheme of scale up in stages 2–4 to produce plants that are sold to growers.

With the application of tissue culture in some propagation schemes, nurseries are able to sell G2 or G3 plants to growers, which should translate into higher health-status plants being

used by the industry. However, for many crops conventional vegetative propagation is still the primary means of plant multiplication that is used. There are several reasons for this: (1) costs for conventional propagation of crops, such as strawberry, where a 300–500 fold increase can be obtained in field production each year, is relatively inexpensive to produce millions of plants; (2) the agency that regulates the certification program may prohibit or limit the number of cycles of tissue culture as a means of propagation due to concerns about somatic mutations; (3) grafted plants may use a rootstock that is generated from seed, which is inexpensive. In such cases, the rootstock may be seed-propagated and the scions by tissue culture or by conventional vegetative propagation methods. During propagation it is important that care is taken to prevent contamination of tools with viruses that are readily mechanically transmitted. Tools are sterilized during tissue-culture propagation to maintain sterile conditions during transfers of tissue-culture plants. It is also necessary in conventional propagation to prevent spread of viruses during the cutting of tubers, rhizomes, taking cuttings, etc. (Lewandowski *et al.*, 2010). Contamination using cutting tools is much more likely in herbaceous crops, such as potatoes, than in woody crops like grapevines, tree fruits, nut crops, etc.

There are efforts among regional plant protection organizations (RPPOs) to harmonize quarantine standards between the member countries. There are nine RPPOs (Asian and Pacific PPO; Caribbean Plant Protection Commission; Comite de Sanidad Vegetal del Cono Sur; Comunidad Andina; European and Mediterranean PPO (EPPO); InterAfrican Phytosanitary Council; Near East PPO; North American PPO; Organismo Internacional Regional de Sanidad Agropecuaria and Pacific PPO (Roy, 2011)). There are also efforts at harmonizing certification standards across some of the RPPOs, such as for fruit trees and grapevines in NAPPO countries, and the EPPO countries have adopted certification schemes for 20 crops (Roy, 2011; EPPO website). These RPPO-developed standards are often a minimum standard that is required, but member countries can require a more stringent standard internally. Although this is happening at the international level, there are many cases where the harmonization of certification programs within countries has not happened. In countries where these programs are regulated at the province or state level, there are often significant differences between the certification standards. For example, in the United States some states require that the G1 plants for some crops be maintained within protected culture (screenhouse) to minimize vector transmission of pathogens, whereas other states do not require that same level of protection. Also, the type and level of testing required at each level in the certification scheme can vary between states. There is an effort underway to harmonize certification standards for some of the fruit crops across the United States. As these programs are developed, they are looking at certification schemes in other countries and RPPOs with the goal of harmonizing standards on a broader scale if possible.

Seed Propagated Crops

For seed propagated crops, seed is often increased in a country other than where the seed will be planted for food or fiber production. To speed up increase of seed for commercial production many companies grow seed in the northern and southern hemisphere to get two cycles of increase in a single year. As a result, seed is moved between countries on a frequent basis and are potentially exposed to quarantine or certification pests of concern in the country where the final crop is grown. Also, because seed has a long shelf life, it may be moved to several countries before it is planted, or a seed lot may be subdivided and shipped to multiple countries. Many countries have phytosanitary requirements for the movement of seed though requirements for field inspections, sampling, and testing can vary and cause problems if trying to move the seed internationally. The IPPC's ISPM No. 28 provides information on agreed on treatments for a range of regulated plants pathogens and pests (Anonymous, 2007a). The preparation of a phytosanitary certificate is done by the exporting country but must meet the requirements of the importing country.Thus, if a seed lot is being shipped to multiple countries the documentation can become very complicated. IPPC has also developed ISPM No. 12, which covers the reexport of the seed to a third country, where the phytosanitary requirements would have to be met by the original exporting country (Anonymous, 2011). For these reasons, harmonized standards could greatly facilitate seed trade to meet the needs of the increasing globalization of agriculture.

There are a number of agencies for seed testing and accreditation of certification schemes. The testing and accreditation by these agencies are recognized by various countries or groups of countries and provide a mechanism to harmonize seed certification standards for international movement of seed among a group of countries. The Association of Official Seed Analysts, Association of Official Seed Certifying Agencies, International Seed Trade Association (ISTA), National Seed Health System, OECD Seed Schemes (US), Society of Commercial Seed Technologists are all involved in seed testing and are recognized by multiple countries. ISTA testing and accreditation is recognized by more than 70 countries. NAPPO regional standards for phytosanitary measures No. 36 provides information on the movement of seed between countries in North America (Anonymous, 2013).

For seed production, the emphasis is on eliminating pathogens from the elite germplasm that can be transmitted through seed or contaminate the seed surface, including viruses, bacteria, and fungi. In many cases, elite germplasm of seed crops is produced and maintained by private companies. With seed certification, genetic purity is often as great a concern as pathogen contamination. There are multiple levels in certification programs for seed crops, similar to those used for vegetatively propagated crops. The seed crops would clearly fit under the G terminology shown in **Figure 1**, and in this case G would stand for generation in the true sense of the word. The four common levels in seed certification (AOSCA) include: Breeder Seed (seed controlled by the plant breeder, or the institution or company where the breeder works), Foundation Seed (propagated from Breeder Seed under conditions that retain genetic purity, identity, and health status), Registered Seed (propagated from Breeder or Foundation Seed under conditions that maintain genetic purity, identity, and health status), and Certified Seed (progeny of Breeder, Foundation or Registered Seed and grown under conditions that maintain

genetic purity, identity, and health status). In addition to genetic purity, identity, and health status, seed certification also requires information on percentage germination, date of germination test, and percentage contamination with other seed.

For pathogens that are transmitted internally in the seed, it is often possible to grow out seed and identify plants free of the pathogen because this type of transmission is rarely 100% efficient (Liu *et al.*, 2014; Mink, 1993). The exceptions to this are the cryptic viruses, which are seed transmitted at 100%. These viruses are not known to cause disease and are not considered in quarantine or certification programs. Heat treatments for eradication of embryo infection by virus have not been successful without a loss in seed viability (Maury *et al.*, 1998). For seed contaminants, various types of seed treatment have been used to eliminate or reduce pathogen level below set tolerances. Dry heat at 35°C for 24 h, followed by 50°C for 24 h, and finally 75°C for 72 h was very effective at controlling very stable viruses, such as tobamoviruses (Tobacco mosaic virus, Tomato mosaic virus, and Cucumber green mottle mosaic virus, Lee, 2004) and potexviruses (Pepino mosaic virus, Ling, 2010) as well as for a wide range of fungal and bacterial pathogens with little or no effect on seed germination (Lee, 2004). Soaking tomato seed for 30 min in a 1% sodium hypochlorite solution (dilution of commercial bleach, depends on the percentage active ingredient in the bleach product) containing 0.1% Triton-X-100 as a wetting agent completely inactivates potexviruses (Pepino mosaic virus; Ling, 2010) on the seed surface with little or no impact on seed germination. Hydrochloric acid or trisodium phosphate were not as effective as bleach in eliminating virus from seed coats (Ling, 2010).

Impact of Improvements in Pathogen Detection on Certification Programs

With woody plants that involve graft transmission assays for detection of viruses, grafted plants may need to be observed for two or more years for symptoms before the plant is determined to be free of the pathogen. These potentially long intervals for detection using biological indexing has prompted most quarantine facilities to adopt laboratory-based testing where possible (Rowhani *et al.*, 2005; Martin *et al.*, 2012; Martin *et al.*, 2013), including: electron microscopy, ELISA, immunospecific electron microscopy, nucleic-acid-based techniques such as PCR or reverse transcription –PCR (RT-PCR) combined with gel electrophoresis and sequencing of the any amplicons obtained, double-stranded ribonucleic acid (dsRNA) detection; and mechanical transmission to herbaceous hosts (Reed and Foster, 2011; Miller *et al.*, 2009). However, with widely used tests currently available, there is still a need for biological indexing onto woody indicators for some exotic pathogens. For many of the crops there are various laboratory tests available for the major pathogens of concern. Thus, in some cases, once all laboratory tests have been completed and found negative, plants are released to the importer on a provisional basis while the biological indexing is completed. This is done with an agreement that in case the tests are positive, the plant will be destroyed. This process allows the importer to begin multiplication of a new cultivar, which in some cases can reduce the time to get the materials to production fields by 2–3 years. The plants must be maintained and propagated under quarantine-approved conditions until all testing is completed.

The currently used assays for virus detection (ELISA, PCR, and q-PCR) are great for detecting a virus in a large number of samples, such as in surveys or ecological or epidemiology studies. However, for quarantine and certification programs a method that was capable of detecting all viruses in a single test would be ideal, rather than doing individual tests for each virus known to infect the host. In some crops, this means 40–60 tests per plant (berries or grapevines). Recent work with macroarrays has shown great promise for detecting the most common viruses in grapevine, with 38 viruses detected in a single test (Thompson *et al.*, 2014).

Potentially, within the next five years as 'Deep' or 'NexGen' sequencing becomes more widely adapted (Studholme *et al.*, 2011; Kreuze *et al.*, 2009), and universal plant microarrays are perfected (Hammond, 2011) they could replace indexing. This would require extensive validation of these technologies to ensure they are as good or better than current methods. The advantage of these technologies is that they have the potential to provide information on any virus in a plant without any *a priori* knowledge of the virus, in contrast to other laboratory techniques that detect known viruses (Kreuze *et al.*, 2009; Al Rwahnih *et al.*, 2009; Kashif *et al.*, 2012; Thekke-Veetil *et al.*, 2013; Seguin *et al.*, 2014; Hammond, 2011; Esteban *et al.*, 2010). Wang *et al.* (2002) demonstrated the feasibility and utility of the microarray technology to identify and characterize new viruses. They developed microarrays containing oligonucleotides that represented conserved sequences of all fully sequenced human respiratory viruses, which at the time represented a few hundred viruses. Using this array they identified a novel Coronavirus and showed that it caused severe acute respiratory syndrome, a newly emerging disease at the time (Wang *et al.*, 2003). NexGen sequencing has a huge impact on many aspects of biology and is used in virus discovery and is being investigated for virus diagnostics. Sequencing of total nucleic acids in plants has led to the identification of multiple viruses and viroids in single plants (Adams *et al.*, 2009; Al Rwahnih *et al.*, 2009, 2011; Kreuze *et al.*, 2009; Sequin *et al.*, 2014) and offers the potential to certify plants as virus-free rather than virus-tested. Obtaining the 'virome' of a plant provides much information on the range of viruses and their diversity within a single plant. However, work with grapevines has shown that many of the viruses were related to mycoviruses rather than plant viruses (Al Rwahnih *et al.*, 2011; Coetzee *et al.*, 2010). This leads to questions on the significance of these viruses in plant health. The new technology will allow for rapid discovery of many new viruses; unfortunately, characterizing the biological significance of these viruses will take much longer. Mycoviruses in grapevines may actually be modifying endophytes and indirectly impacting the health status of grapevines. Thus, eventually how viruses and other microorganisms impact the whole plant (understanding the microbiome) may be important in certification and quarantine, but we are not there yet. Although it is good to know what is in the plant, this technology is resulting in the identification of many new

viruses for which there is no biological information. For the next decade it is likely that the biological significance will lag behind the discovery of microorganisms in plants, and it is important that for certification and quarantine programs, any changes are made in response to the biology of these organisms rather than their presence. It seems reasonable that new plant viruses related to known plant pathogenic viruses should be considered as the highest priority for evaluating their biological significance and determining if they should be part of quarantine and certification regulations.

Certification standards vary widely among crops and regulatory authorities. The viruses included in a certification program can vary from country to country or state to state. An excellent example is grapevines where certification in Italy includes more viruses than programs in Germany or France; or grapevine certification in Washington State is different from California. Some of these differences are due to environmental considerations, where infection by a pathogen may cause severe disease in one setting, such as crown gall in grapevine in New York State, but be latent or symptomless under different environmental conditions, such as crown gall in grapevine in California. Attempts to harmonize certification schemes across boundaries to facilitate trade of plants without increasing trade in plant pathogens will require certification programs to account for disease expression by pathogens in areas where the certified plants may be sold, rather than only where the nursery stock is produced. In the United States, where certification programs are regulated by individual states, there are efforts underway in multiple crops (blueberry, grapevines, hops, *Rubus*, strawberry, and fruit trees) to develop a single certification standard that all states with programs for that crop would adopt. If successful, this in essence would provide a national program for certification of these crops. As this process is developing, there is an ongoing communication with trading partners to harmonize these standards as much as possible with their certification programs to facilitate international trade.

Plant Abiotic Stress: Salt

A Läuchli and SR Grattan, University of California, Davis, CA, USA

© 2014 Elsevier Inc. All rights reserved.

Glossary

Electrical conductivity (EC) An indicator of the salinity in the water and is directly related to the salt concentration in the water. EC_e is the electrical conductivity of the saturated soil solution and EC_w is the electrical conductivity in the irrigation water.

Exchangeable sodium percentage The percentage of sodium (Na^+) occupying the total cation exchange sites on the soil.

Osmolytes Low molecular weight solutes (sugars, organic acids, amino acids, and other solutes) that are dissolved in solution lowering the osmotic potential of that solution. Organic osmolytes play an important role in osmotic adjustment.

Relative water content (RWC) The water content of a given amount of leaf relative to its fully hydrated or fully turgid state giving an indication the hydration state of the leaf. RWC = (fresh leaf wt. − dry wt.)/(turgid leaf wt. − dry wt.).

Salt overly sensitive (SOS) A coordinated signaling pathway comprised of SOS1, SOS2, and SOS3 transport proteins in the cell that some plants have as a means of maintaining ion homeostasis when exposed to salt stress.

Sodium adsorption ratio (SAR) A measure of the sodicity of the water. $SAR = Na^+/(Ca^{2+}+Mg^{2+})^{1/2}$ when units are in mmol l^{-1}.

Water potential The potential energy of water at any point within the soil–plant–water system. This energy potential is comprised collectively of osmotic, matric, elevation, and pressure components.

Introduction

The vast majority of crops grown in the world are glycophytes, or nonhalophytes. These plants are adversely affected in saline conditions unlike the halophytes, which thrive under these harsh environments. As a consequence, crops endure salt stress, a condition where the plant is unable to express its full genetic potential for growth, development, and reproduction, as the salinity in the soil exceeds critical levels (Läuchli and Epstein, 1990; Grieve *et al.*, 2012). However, there is no sharp distinction between salt stress and lack of stress. Rather, there is a gradual continuum from the absence of stress at low salinity to severe stress at high levels of salinity. In some plants, a beneficial response at low levels of salinity may even be observed (Kronzucker *et al.*, 2013; Shabala and Munns, 2012). Plants, however, vary widely in their tolerance to saline and sodic conditions as well as genotypes within a species even though there is no clear distinction between salt tolerance and salt sensitivity. A salt-stressed plant shows visual (e.g., leaf injury) or quantitative (e.g., reduced growth) signs of being adversely affected. This depends not only on the intensity of the salt stress but also on the chemical composition of the saline substrate and presence of other abiotic and biotic stresses such as temperature, water deficit, flooding, nutritional inadequacies, poor soil physical conditions, pests, and pathogens (Mittler, 2006). Thus, plants under field conditions often endure multiple stresses that show potential interactions, which can be both negative and positive (Läuchli and Grattan, 2007).

This article provides a general overview of plant responses and mechanisms to salinity and sodicity stress and focuses on agronomic crops and how the whole plant integrates these responses and mechanisms. Although this article does not focus much on biochemical and molecular mechanisms of salt tolerance or on genomics-type technologies, such emphasis can be found in a review by Munns and Tester (2008).

Salinity and Sodicity

Before plant response to salt stress can be addressed, it is important to address the chemical and physical edaphology of the saline environment. Soils and irrigation water sources contain mineral salts, but the concentration and composition of the dissolved salts vary from one location to another (Tanji and Wallender, 2012). In solution, these salts dissolve and form positively charged cations and negatively charged anions. The most common cations are calcium (Ca^{2+}), magnesium (Mg^{2+}), and sodium (Na^+), whereas the most abundant anions are chloride (Cl^-), sulfate (SO_4^{2-}), and bicarbonate (HCO_3^-). Potassium (K^+), carbonate (CO_3^{2-}), nitrate (NO_3^-), and trace elements also exist in water supplies and soil solutions but most often concentrations of these constituents are comparatively low. In addition, some ground water sources contain boron (B) at comparatively low concentrations but nevertheless at levels that may be detrimental to certain crops.

Saline and sodic environments are sometimes used interchangeably, which is incorrect. There is a clear distinction between salinity and sodicity; the former being related to salt concentration and the latter to salt composition. Salinity refers to the concentration of salts in the irrigation water or soil that is sufficiently high to adversely affect crop yields or crop quality. These adverse responses are caused by high concentrations of salts in the soil solution (i.e., osmotic effects) or by high concentrations of specific ions such as chloride or sodium that can cause specific injury to sensitive crops (i.e., specific-ion effects). Sodicity, however, is related to the proportion of

sodium in water, or adsorbed to the soil surface, relative to calcium and magnesium. Sodic water is synonymous with 'soft' water. Sodicity can contribute to the deterioration of physical properties of the soil, which can indirectly affect plants resulting in surface crusting, reduced water infiltration, and reduced aeration causing anoxic or hypoxic conditions for roots.

Sodicity has been described in different ways (Jurinak and Suarez, 1990). The sodicity of soil is characterized by the exchangeable sodium percentage (ESP). The ESP is the percentage of the soil's cation exchange capacity occupied by sodium (Na^+). The sodicity of water, however, is a measure of the sodium adsorption ratio (SAR), and is defined as

$$\mathrm{SAR} = \frac{\mathrm{Na}^+}{\sqrt{(\mathrm{Ca}^{2+} + \mathrm{Mg}^{2+})}} \quad [1]$$

where concentrations of the cations are in mmol l^{-1}. The ESP and SAR are related to one another and, for most practical purposes, are numerically equivalent in the range of 3–30 (Richards, 1954).

Sodic soils affect almost all crops because of the deterioration of soil physical conditions (Shainberg and Singer, 2012). Dispersion of soil aggregates in sodic soils decreases soil permeability to water and air, thereby reducing plant growth. However, the break down in soil structure is not related to SAR alone. The deterioration of physical conditions of the soil depends on the SAR and the electrical conductivity of water (EC_w). The electrical conductivity is an indicator of the salinity of water and is directly related to the ionic concentration of water. Figure 1 shows the relationship between the SAR and EC_w of the irrigation water. Irrigation water with both low salinity (e.g., low EC_w) and high SAR is particularly problematic (see the red zone). However, water with low SAR and high salinity has better infiltration (see the blue zone), even though the higher salt concentration could damage crops. Therefore, water infiltration rates decrease with decreasing soil salinity and with increasing exchangeable Na^+, or sodicity. Moreover, water very low in electrolytes, regardless of the SAR, can be damaging to the soil structure. Many river waters derived from snowmelt, such as California's Sierra Nevada mountains ($EC_w < 0.1$ dS m^{-1}), are notorious with this unique characteristic.

These deteriorating processes occur due to the combination of clay swelling and instability of soil aggregates (Shainberg and Singer, 2012). In addition, clay movement and deposition into soil pores reduces the fraction of large pores in the soil. Large pore size distribution is important for water movement, adequate drainage, and proper aeration. It is important to note that factors other than EC_w and SAR affect the physical properties of the soil. Factors, such as soil texture, mineralogy, organic matter, pH, and rates of soil wetting (Shainberg *et al.*, 2001; Shainberg and Singer, 2012), can have a large influence on the overall processes affecting soil deterioration.

Principal Responses of Plants to Salinity

Overall Plant Reponses

There are two properties of saline media that adversely affect crops. Salinity depresses the external water potential (osmotic effect) and particular ions in the solution may have chemical or specific-ion effects. Although these properties are often

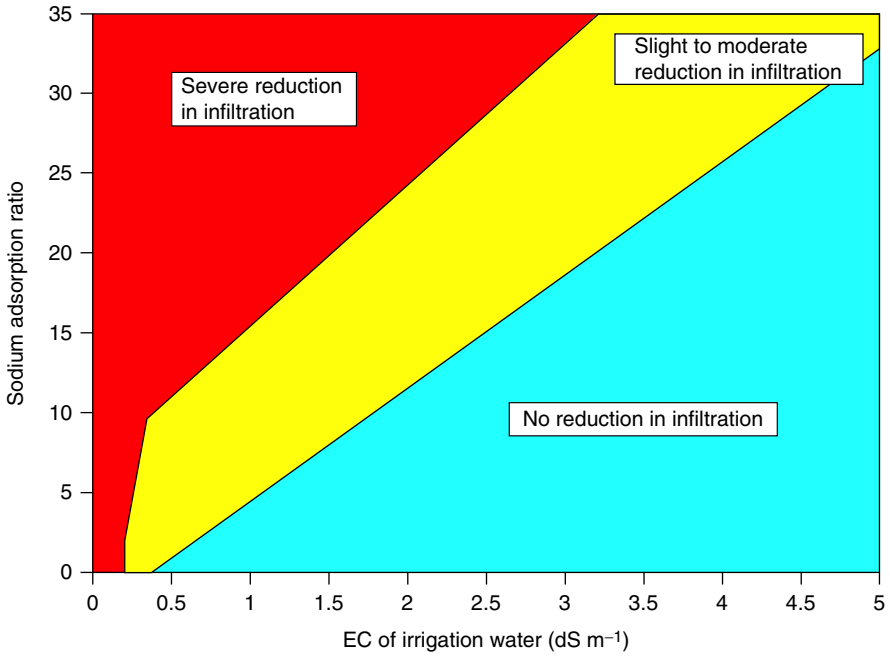

Figure 1 Relationship between salinity (EC) and sodicity (SAR) of irrigation water and its potential effects on water infiltration in the soil. Adapted from Ayers, R.S., Westcot, D.W., 1985. Water quality for agriculture. FAO Irrigation and Drainage Paper 29 Review 1, pp. 174. Rome: Food and Agriculture Organization of the United Nations.

discussed separately, usually both are implicated. A scheme that illustrates the effects of salinity on plants is shown in Figure 2. The left and right parts of Figure 2 suggest that some effects of salinity on plants are not deleterious. With few exceptions, however, saline conditions adversely affect crops.

Depression of the external osmotic potential by high salt concentrations tends to narrow the gap between the water potentials inside and outside the root cell. At high salinities, the external osmotic potential may be depressed below that of the cell water potential, resulting in osmotic desiccation. Even in less extreme situations, the water availability to the plant will at least initially tend to be lessened. The reduction in the osmotic potential of the medium is one of the primary causes of the adverse effects of salinity on plant growth. The plants exert considerable amounts of energy to transport, sequester, and exclude ions as well as synthesize and concentrate compatible solutes so that cells can osmotically adjust. This energy expenditure is at the expense of plant growth.

Salinity may also positively affect plant growth and crop quality. It may promote the growth of halophytes (Flowers and Colmer, 2008) or enhance quality of crops such as improved freezing tolerance of citrus (Syvertsen and Yelenosky, 1988), increased sugar content in carrots, increased soluble solids in tomatoes and melons, and improved grain quality in durum wheat (Grieve *et al.*, 2012).

As illustrated in Figure 2, these specific ion effects may be categorized under three headings. First, high concentrations of a given ion may cause mineral nutrition disorders. For example, high Na^+ concentrations, which create a sodic condition, may cause deficiencies of other elements, such as potassium or calcium. Second, certain ions, such as sodium or chloride, may have direct toxic effects, which may not always be clearly distinguishable from nutrient deficiencies. Third, there may be positive specific-ion effects that promote the growth or qualitative features of the plant such as succulence or pigment composition. These three types of specific-ion effects are not mutually exclusive but may manifest themselves on the plant at the same time to various degrees.

Sodicity is due to a high activity of Na^+ in the soil solution, relative to activities of Ca^{2+} and Mg^{2+}. Sodicity may, therefore, cause two of the effects discussed in connection with salinity; disturbances of mineral nutrition and toxicity; and there are indirect effects as well. Sodicity will not elicit strictly osmotic effects but, as described in the Section Salinity and Sodicity, can affect soil physical properties leading to crusting, reduced infiltration, and reduced aeration, which can also adversely affect plants (Shainberg and Singer, 2012).

Diversity of Plant Responses to Salinity

Plants show large diversity in their response to salinity (Grieve *et al.*, 2012; Shabala and Munns, 2012). Most crop plants are glycophytes and are relatively sensitive to salinity in

comparison to halophytes. Nevertheless, among crop plants there is considerable diversity in salt tolerance. Some crops like asparagus, barley, canola, sugar beet, and Swiss chard are tolerant of salinity whereas bean, carrot, onion, rice, and strawberry are sensitive to salinity. The salt tolerance of a crop can be described as a function of the percentage of yield decline across a range of salt concentrations relative to a nonsaline control (Grieve *et al.*, 2012). Although nonlinear models have been used to describe yield reduction with increased salinity, salt tolerance can be adequately described on the basis of two parameters. First is the 'threshold salinity,' which is the maximum salinity expressed as the electrical conductivity (EC_t) of the soil solution above which relative yields decline. Second is the slope of expected yield reduction per unit increase in salinity above the 'threshold' value. The yield potential (% yield) of this biphasic response can be expressed as

$$\text{Yield potential } (\%) = 100 - b(EC_e - a) \qquad [2]$$

where '*a*' and '*b*' are the 'threshold' and 'slope' values, respectively, specific for different crops. For example, Figure 3 illustrates the yield responses for alfalfa (lucerne), barley, corn (maize), rice, and wheat in relation to increased salinity. These response functions illustrate differences in salt tolerance mainly due to differences in osmotic effects among these important crops (Grieve *et al.*, 2012). These crops were salinized with a balanced mixture of salts and optimal nutrition minimizing specific ion effects. It is noted that rice and corn are considerably more sensitive to salinity than are wheat and barley. The tolerance of alfalfa, an important forage crop, falls between that of rice and wheat. Many horticultural fruit and nut crops such as almonds, apples, citrus, peaches, and plums tend to be sensitive to salinity. For a more complete list of crop tolerances and tables with specific '*a*' and '*b*' values, refer to Grieve *et al.* (2012). Using these '*a*' and '*b*' values and eqn [2], lines of other crops can be plotted similar to those selected in Figure 3.

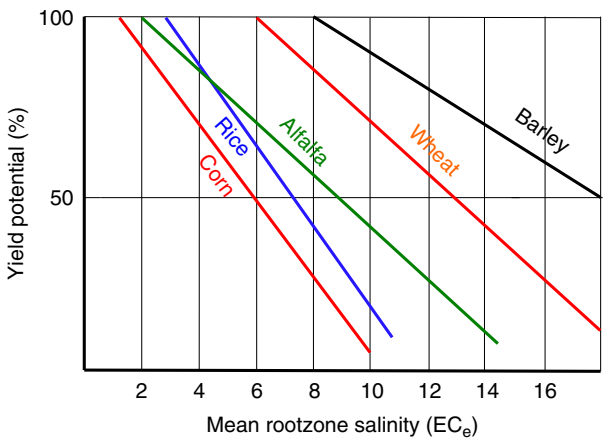

Figure 3 Relative yields of important world crops in relation to increased salinity (EC_e), where EC_e is the electrical conductivity of the saturated soil paste from soil samples collected in the active root zone. Reproduced from Grieve, C.M., Grattan, S.R., Maas, E.V., 2012. Plant salt tolerance. In: Wallender, W.W., Tanji, K.K. (Eds.), Agricultural Salinity Assessment and Management. ASCE Manuals and Reports on Engineering Practice No. 71, pp. 405–459. Reston, VA: American Society of Civil Engineers.

Unlike glycophytes, halophytes are the native flora of extremely saline soils and are distributed among several families of flowering plants, for example, pickleweed (*Salicornia* spp.), the salt bushes (*Atriplex* spp.), and mangroves (several genera) (Flowers and Colmer, 2008). Most halophytes only grow well in the presence of salt, and among the most salt-tolerant halophytes many can grow at salinities at or above seawater. A general physiological feature of halophytes is their capability to accumulate salt in specific compartments such as cell vacuoles, where it can be used for osmotic adjustment (see Section Osmotic Effects and Adjustment) whereas the relatively salt-tolerant glycophytes feature salt exclusion as a mechanism of tolerance. If response relationships of these halophytes were to be plotted in Figure 3, not only would there be a stimulatory effect with modest increases in salinity, but also the curves would fall further to the right of barley.

Physiological Mechanisms of Salinity Tolerance in Plants

Overall, salt tolerance in plants is determined by three distinct features: (1) osmotic tolerance, (2) ability to exclude Na^+ or Cl^-, and (3) ability of the tissue to tolerate high concentrations of Na^+ or Cl^- (Munns and Tester, 2008). Very often salt-tolerant plants will have one feature, but not the other. However, it is possible that salt-tolerant plants exhibit more than one of these features.

Osmotic Effects and Adjustment

Plant growth is inhibited by salinity through osmotic stress and a decrease in cell turgor. If the osmotic potential of the external medium were to immediately drop lower than that of the plant's cells, the cells would lose turgor and suffer osmotic desiccation. To maintain normal growth, plants must reduce their internal water potential to adjust to the drop in external osmotic potential. Osmotic adjustment can be achieved by (1) the absorption and accumulation of ions from the medium or (2) by synthesis and accumulation of organic solutes. Both processes occur but the extent by which one process dominates over the other is dependent on the type of plant and level of salinity.

Unlike glycophytes, halophytes are adapted to high saline environments by absorbing salt from the medium and using it as its major internal osmoticum (Flowers and Colmer, 2008). However, salt in plant cells can be toxic. A number of evidences indicate that high salt concentrations in the cytoplasm damage enzymes and organelles (Greenway and Munns, 1980). Salts absorbed from the soil solution apparently serves as an osmoticum in the vacuole, a membrane-bound compartment that occupies a large portion of the cell volume. In the cytoplasm, the function of osmotic adjustment is served mainly by organic solutes synthesized by the plant (Wyn Jones and Gorham, 2002). Thus, organic osmolytes are used to a large extent in only a small fraction of the total cell volume. The tonoplast (the membrane that separates the vacuole from the cytoplasm) must transport salt out of the cytoplasm and into the vacuole where it can concentrate while at the same

time prevents any substantial leakage of organic osmolytes from the cytoplasm into the vacuole.

Anatomical adaptation is a common feature among many halophytes as a means of tolerating highly saline environments (Shabala and Munns, 2012). Most of these adaptations are related to Na^+ sequestration or Na^+ secretion, but some other features are worth mentioning (Shabala and Munns, 2012). Leaf succulence describes leaf tissue thickening and is accompanied by increases in leaf sap volume causing an increase in cell size. This is particularly characteristic of mesophyll cells and hence their vacuoles are also larger. Larger vacuoles provide a more efficient means of Na^+ removal from the cytoplasm as there is more room for this toxic element to be sequestered. Salt glands and salt bladders are remarkable anatomical features on some halophytes that eliminate salt by literally expelling salts outside the plant or by sequestering excess salt from metabolically active tissues (Flowers and Colmer, 2008). A more detailed description of the anatomical effects caused by salinity and function of salt glands and salt bladders, is presented by Shabala and Munns (2012).

The glycophytes, unfortunately, are unable to cause the sharp asymmetrical intracellular compartmentation of inorganic and organic solutes that is central for the adaptation of salt-absorbing halophytes to their saline habitats. Exposed to moderate salinities, glycophytes tend to exclude Na^+ or Cl^- and to sequester what little salt they absorb in the roots and stems. Salt exclusion minimizes the exposure of the leaf cells, and hence the photosynthetic apparatus, to salt. Thus, the glycophytes regulate ion fluxes less effectively at the cellular level than do halophytes, but partition ions more effectively at the organ and tissue levels. Regardless, glycophytes do show differences in their ability to partition salt at the cellular level and this ability is related to salt tolerance. For example, Barley, a relatively salt-tolerant crop, can tolerate Na^+ concentrations up to 500 mmol l^{-1} in the leaf tissue primarily by sequestering this toxic ion in vacuoles; whereas the more salt-sensitive durum wheat are unable to partition Na^+ in vacuoles as effectively (Munns *et al.*, 2006).

To survive in saline conditions, overcoming their inability to absorb major quantities of external ions for osmotic adjustment, glycophytes must synthesize organic osmolytes called compatible solutes, by increasing their uptake, or by *de-novo* synthesis of such compatible solutes and concentrate them in the cytoplasm. Many such organic solutes have indeed been identified and are listed in **Table 1**. The term 'compatible solutes' is often applied to these organic compounds because of their compatibility with cytoplasmic entities and processes and do not interfere with cellular metabolism even at high concentrations (Bray *et al.*, 2000). Compatible solutes that commonly accumulate to high concentrations in plants are proline, glycine betaine, and sucrose (Munns and Tester, 2008). To function as compatible osmolytes, these solutes are highly compartmentalized in plant cells. The vacuoles accumulate charged ions and solutes that would otherwise perturb metabolism if accumulated in the cytoplasm. Compatible solutes in the cytoplasm, however, allow the cytosol to be osmotically balanced with the vacuole. As an example, very little glycine betaine (<1 mmol l^{-1}) is contained in the vacuoles of spinach leaves under salt stress, but its concentration in the cytosol and chloroplasts may reach 300 mmol l^{-1} (Bray *et al.*, 2000). At low concentrations, these organic solutes can function as 'osmoprotectants' (McNeil *et al.*, 1999).

Table 1 Compatible solutes (osmolytes) of higher plants

Class of compounds (1)	*Major compounds (2)*
Amino acid	Proline
Quaternary ammonium compounds	Glycine betaine
	Proline betaine
	β-Alaninebetaine
	Choline-O-sulfate
Polyhydric alcohols	D-Sorbitol
	D-Mannitol
Mono- and disaccharides	Sucrose and fructose
Cyclitols	D-Pinitol
	D-Ononitol
	L-quebrachitol
	Myo-inositol
	Trehalose
Tertiary sulfonium compounds	3-Dimethylsulphonio propionate

In addition to organic solutes, glycophytes can adjust osmotically by increasing the accumulation of inorganic ions such as K^+, Na^+, and Cl^-. Ion accumulation is the preferred method of adjustment because it is cheap energetically. However, the accumulation of inorganic solutes should not inhibit cell metabolism. K^+ ions can play this role, whereas Na^+ and Cl^- can only fulfill this role at low external concentration, as these ions are toxic to cell metabolism at higher concentration unless they are sequestered in cell vacuoles and away from metabolic activity as they are in halophytes.

The synthesis and transport of organic osmolytes, the transport of inorganic ions, and the compartmentation of organic and inorganic solutes, all require the expenditure of metabolic energy, that is, photosynthate (Epstein, 1980). Stavarek and Rains (1985) compared the performance of alfalfa cells selected for salt tolerance in cell culture with that of unselected (nontolerant) cells. At 170 mmol l^{-1} NaCl, the unselected cells grew very slowly. The selected (salt-tolerant) cells at the same salinity differed from those in the control treatment (no salt) only in having a lag period of a few days. Thereafter, their growth (i.e., gain in dry weight) paralleled that of the cells in the control treatment. Measurements of carbohydrate metabolism of the salt-tolerant selected cells showed maintenance costs to be relatively low when the cells grew under saline conditions. The maintenance costs of the unselected cells increased with salinity. Even selected cells, however, must divert energy to the processes of ion transport, synthesis of organic osmotica, and compartmentation. These costs result in diminished growth per unit of substrate (sugars) utilized (Stavarek and Rains, 1985; Yeo, 1983). Plants vary greatly in the adjustment of their energy economy to the presence of salt (Schwarz and Gale, 1981), which manifests into plants with different salt tolerances. Maintenance respiration rates usually increase at moderate salinities. The definition of 'moderate,' however, depends on the salt tolerance of

the plant. Raven (1985) concluded that the energy cost of the synthesis of compatible solutes leads to a potential growth penalty. The adenosine triphosphate (ATP) requirement for the synthesis or accumulation of solutes in leaf cells has been estimated by Raven (1985) to be approximately 3.5 mol for either Na^+ or Cl^-, 41 for proline, 50 for glycine betaine, and 52 for sucrose, respectively. ATP is the basic biochemical high-energy compound used in metabolic processes. Hence, the synthesis of organic, compatible solutes proceeds at the expense of growth, but it may allow the plant to survive (Munns and Tester, 2008).

Specific Ion Effects: Toxicity

In a number of instances, toxicity of specific ions is supported by evidence from two sources. One is that moderate concentrations of sodium, chloride, sulfate, or other ions reduce growth or cause specific injury. The other is that isosmotic solutions of different compositions may elicit different responses. As might be expected, genotypes may differ in these responses even within a species.

Toxicities due to even moderate concentrations of some ions in salt-affected soils are most common in woody plants, particularly tree crops and vines. Color photographs, depicting various degrees of leaf injury due to sodium and chloride toxicity in several fruit crops, are shown in a publication by Bernstein (1965). These woody crops have little ability to exclude sodium or chloride from their leaves and the plants are long-lived; hence, they often suffer toxicities at even moderate soil salinities.

Ion toxicities are not exclusive to woody crops. An example from experiments with wheat shows the usefulness of isosmotic solutions of different ionic composition, as well as the importance of the genotype. Kingsbury and Epstein (1986) found that the growth of a salt-sensitive line of wheat was adversely affected by nutrient solutions containing high concentrations of Na^+ (>100 mmol l^{-1}), but not by isosmotic solutions without Na^+ at elevated concentrations. The growth of a line selected for salt tolerance was unimpaired by any of the solutions used. Termaat and Munns (1986) also used isosmotic solutions to investigate osmotic versus specific ion effects.

Specific Ion Effects: Nutrition

The presence of high concentrations of sodium and chloride is a common feature in many salt-affected soils. The ratios of these ions to other nutrient ions in the soil solution may be quite high and may cause specific nutrient deficiencies in the plant (Läuchli and Epstein, 1990). Thus, plant performance may be adversely affected by salinity-induced nutritional disorders, resulting from salinity effects on nutrient availability, competitive uptake, transport, or partitioning within the plant (Grattan and Grieve, 1999). For example, in the saline environments in which sodium predominates over potassium, the plant's paramount nutritional requirement is acquiring potassium in adequate amounts (Rains and Epstein, 1967).

Saline conditions may inhibit the absorption of nitrate. Thus, in short-term experiments (up to 12 h) with barley seedlings, Aslam *et al.* (1984) found that SO_4^{2-} and, to a greater extent, Cl^- diminish the rate of NO_3^- absorption, the degree of inhibition being 83% at 200 mmol l^{-1} Cl. Chloride's effect on NO_3^- absorption was apparent within 1 min and the identity of the accompanying cation (Na^+ or K^+) had little effect on this inhibition. Salt did not affect subsequent NO_3^- reduction by the plant.

Sodium ions have been shown to cause disturbances in calcium and potassium nutrition. Excess sodium in the soil solution has been found to reduce both of these nutrient cations (Grattan and Grieve, 1999). Nutritional disorders involving other elements may be linked to the effects of salinity on the uptake, transport, and metabolism of calcium. High Ca^{2+} concentrations in the soil substrate may mitigate the effects of salinity. High ratios of sodium to calcium in the medium tend to be deleterious. Inadequate concentrations of Ca^{2+} may adversely affect membrane function and growth even within minutes of salt application (Läuchli and Grattan, 2012; Shabala and Munns, 2012). More details on sodium-induced calcium deficiencies are found in the Section 'Integrating the Whole-Plant Response.'

Integrating the Whole-Plant Response

Response to Salinity Stress during Plant Development

It has long been recognized that a crop's sensitivity to salinity varies from one developmental growth stage to the next (Bernstein and Hayward, 1958). The majority of the research indicates that most annual crops are tolerant at germination but are sensitive during emergence and early vegetative development (Läuchli and Epstein, 1990; Grieve *et al.*, 2012). As plants mature, they become progressively more tolerant to salinity, particularly at later stages of development. Salinity affects both vegetative and reproductive developmental processes in the plant. This is particularly important depending on whether the harvested organ of the crop is a stem, leaf, root, shoot, fruit, fiber, or grain (Läuchli and Grattan, 2007).

Germination and seedling emergence
